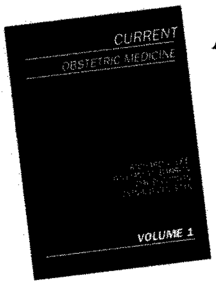
Current Obstetric Medicine, Volume 1
Premier Edition

In the Pregnant Patient + Medical Disorder equation, where do you fit in?



A pregnant patient with a medical disorder poses a unique and special challenge. You need to understand her disease and how it affects her pregnancy. You also need to recognize the physiologic signs of a normal gestation in order to best treat her overall condition.

In this premier volume of **Current Obstetric Medicine**, international authorities discuss recent developments in obstetric medicine, summarizing pertinent findings and trends from the literature published within the last two years. They also add their own critical commentary, providing new perspectives on the problems you face. Concentrating on emerging treatments and insights, the authorities focus on how these innovations affect your patients and your practice. This combination of the latest research and expert interpretation makes **Current Obstetric Medicine, Volume 1** a vital clinical reference.

You'll get a multidisciplinary perspective of new diagnostic techniques and therapies, such as preconception counseling and management of asthma, rhinitis, and anaphylaxis during pregnancy. A wide spectrum of conditions and problems are covered, including renal disease, postpartum thyroiditis, diabetes, and accidents. And each issue in **Current Obstetric Medicine** is discussed in terms of its clinical significance—so you can start applying the best available treatments to your patients' care immediately.

To review this outstanding resource ***free for 30 days****, simply mail the Free Examination Certificate below or call* ***Toll-Free 1-800-426-4545*** *(To speed your order, mention code "MCA-029"). If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It's an easy way to place yourself in the patient care equation.*

FREE EXAMINATION CERTIFICATE

Please send me **Current Obstetric Medicine, Volume 1** (21178). I understand that I will pay $59.95* plus shipping and handling if I decide to keep the book.
* Resident price $40

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.

—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.

—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.

—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.

—Human experimentation has been approved by the local institution as stated in the Methods section.

—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.

—The covering letter with essential information is with the manuscript.

—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.

—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.

—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.

—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.

—Title.

—Author(s) name(s) and highest academic degree(s) are shown.

—City(ies), state(s), and country other than U.S. in which the study was conducted are given.

—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.

—Acknowledgment of financial support is cited.

—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.

—If reprints will not be available, this has been stated on the title page.

—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.

—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.

—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

The responsible author(s) must be named____________________ (Type name) ____________________ Signature

Each author's name must be typed underneath the signature.

THE GOOD THINGS SHE DOES FOR HERSELF, SHE STAYS WITH…

She stays with TRIPHASIL®
for the same reasons
she started with it:

- Minimal breakthrough bleeding from Day 1
- Low estrogen dose
- Low incidence of common OC side effects*

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

Worldwide Leadership in Female Healthcare
WYETH-AYERST LABORATORIES
Philadelphia, PA 19101

© 1991, Wyeth-Ayerst Laboratories.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. See prescribing information.

See brief summary on adjacent page.

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:

TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

> **Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.**
>
> The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days. For full details on dosage and administration see prescribing information in package insert.

EDITORIAL

Structured abstracts

After one year of thoughtful discussion the Editors of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY have decided to introduce structured abstracts. We believe that they will be of benefit to both readers and authors. The reader will have at a glance many of the salient facts about a given article. We would be very disappointed if the structured abstract induced the reader to read only the abstract and feel that he/she had thereby received all the information that the author(s) wished to impart; this is not the case. Background, fact, and discussion that cannot possibly be included in the abstract are contained in the full article. Reading only the essence of an article is like smelling a flower and not taking the time to enjoy the beauty of its color and form; you have deprived yourself significantly.

The structured abstract, limited to 150 words, will have four essential parts: **OBJECTIVE(S), STUDY DESIGN, RESULTS,** and **CONCLUSIONS.** These four parts are to be typed as separate headings. The **objective(s)** section should state in a concise manner why the study was done. In many articles it will be the hypothesis being tested, while in others it should point out why the case or technique is being reported—how it might help the reader diagnose a case or manage a patient. The **study design** section should include the locale of the study, the number and type of human subjects, nonhuman species, or material being studied, the principal test(s) performed, and the types of statistical analyses if appropriate. The **results** are those principal results that confirm or refute your hypothesis. When statistical analyses are mandatory for the report, the statistical validity of the results must be included. The **conclusions** should state in a concise way the effect of the study on patient management, our understanding of basic processes within the organism, or the way in which we teach students or patients; in short, the value of the article to the reader.

It was stated earlier in this editorial that the structured abstract may be of value to the author(s). The principal value that we see is in encouraging the author(s) to identify before or early in the study the hypothesis being tested. If that is the case and the study design is rigorously fit to the hypothesis, authors can avoid submitting incomplete manuscripts for possible publication.

The abstracts for all articles, including society articles, will conform to the above structure, with the exception of Clinical Opinions, Current Developments, brief communications, case reports, and other articles that do not contain a Results section. Abstracts for those articles should follow the standard abstract format. The limit of 150 words still applies, except for case reports and brief communications, which are limited to 50 words.

Home monitoring of uterine contractility

Summary of a workshop sponsored by the National Institute of Child Health and Human Development and the Bureau of Maternal and Child Health and Resources Development, Bethesda, Maryland, March 29 and 30, 1989

George G. Rhoads, MD, MPH, Donald C. McNellis, MD, and Samuel S. Kessel, MD, MPH
Bethesda, Maryland

At an interdisciplinary workshop on home monitoring of uterine activity, participants reviewed the basis of this technology and its use in the identification of women at high risk of preterm delivery and in the prevention of preterm birth. Although the guard-ring devices in current use appear capable of detecting uterine activity, they do not clearly distinguish between Braxton Hicks contractions and the contractions of early labor. There was agreement that women destined for preterm delivery have more uterine activity on average than do other women of comparable gestational age but that there is substantial overlap between the two groups. Thus it is uncertain whether this difference can be used effectively for screening purposes. Conferees agreed that there is considerable evidence that twice-daily monitoring of very-high-risk women, in conjunction with daily nursing support and high-quality obstetric care, may prevent preterm births. Available evidence does not clearly distinguish the contribution of tocodynamometry from that of nursing support. A number of areas were identified in which further research is needed. (AM J OBSTET GYNECOL 1991;165:2-6.)

Key words: Preterm delivery, tocodynamometry, uterine monitoring

For some years physicians have been using external tocodynamometers in labor and delivery suites as a convenient, noninvasive method of assessing uterine activity. A number of studies have shown that the tracings obtained with these devices correlate reasonably with direct measures of intrauterine pressure obtained during active labor and provide good estimates of the frequency and duration of contractions, as well as some indication of intensity.

Because patterns of or frequency of low-grade uterine activity may serve as indicators of impending preterm labor, the use of external tocodynamometers to assess risk and to diagnose labor at an early stage has been an attractive concept. Several manufacturers have developed portable devices that are suitable for home use and that allow the transmission of digitized tracings over telephone lines to a remote site for interpretation. Thus women at high risk of preterm labor can be monitored at home, and the resulting information can be made available for use by their physicians. Such home monitoring has been used primarily in conjunction with substantial nursing support that has included instruction in the use of the monitor and daily telephone calls to assess patient symptoms and to ensure smooth transmission of the tracings. Randomized[1-3] and nonrandomized[4] trials in high-risk women have revealed significant reductions in the frequency of preterm births in those patients who received the combined monitoring and nursing services when compared with those who received standard obstetric care. However, these trials have been subject to criticism because of their small size and their failure to separate the effects of the monitor from those of nursing support.

To clarify what is known and what is not known about home monitoring of uterine activity, the National Institute of Child Health and Human Development and the Bureau of Maternal and Child Health and Resources Development convened a workshop on March 29 and 30, 1989, in Bethesda, Maryland. Participants with backgrounds in physiology, bioengineering, mathematics, obstetrics, pharmacology, and epidemiology reviewed the potential limitations and utility of this ap-

proach to the prevention of preterm labor from the perspective of their various disciplines. Six major areas were discussed: animal studies of uterine activity, sensitivity and standardization of noninvasive sensors of uterine activity, uterine contractions during normal human pregnancy, occasional monitoring of the frequency of contractions during pregnancy as an approach to assessing the risk of preterm labor, early diagnosis of preterm labor by daily monitoring, and aspects of tocolytic therapy that are related to a monitoring program.

The current state of the art

It is well known that poorly coordinated, relatively weak uterine contractions occur throughout pregnancy in all mammalian species that have been studied. In the rhesus monkey these epochs of activity, which have been called uterine *contractures*, are easily distinguished by the accompanying electromyographic and intrauterine pressure changes from uterine *contractions* associated with labor.[4a] Contractures are less well synchronized than contractions and often do not involve the whole uterus. Although similar studies have not been done in women, it is reasonable to conjecture that normal Braxton Hicks activity is of the contracture type. The switch from contractures to contractions in gravid monkeys usually occurs around the onset of darkness for a few days before labor begins. Each night the frequency and intensity of contractions increase. In addition, the time period during which contractions occur is longer. Eventually, if all the other features of labor (especially cervical dilatation) occur, delivery will follow. It is, of course, uncertain whether a similar change in the uterine electromyographic pattern occurs in women, and the monitors that have been available for use in humans before labor have not clearly distinguished between these two types of activity.

The tocodynamometers that are available for human use before the rupture of membranes are external devices that are usually held against the abdominal wall with a belt. The excursion of a central piston that is applied to the skin under spring force is measured. As the uterus contracts, the uterine wall becomes more resistant to indentation by the piston, and the resulting piston movement is recorded electronically. Smyth[5] argued some years ago that it is advantageous to mount the piston in the center of a flat plate (the guard-ring arrangement), and the conferees agreed that this type of instrument provided a better record than did other types of external tocodynamometer. Nearly all published information on ambulatory tocodynamometry concerns the guard-ring device.

Validation of the records from external tocodynamometers has been obtained from women in labor by use of intrauterine pressure catheters. In that setting the external instrument has provided excellent data on contraction frequency ($r > 0.9$) and very good data on the duration of contractions. Some investigators have reported a good correlation between the amplitude of the deviations on the external tracing and internal pressure excursions, but where no internal catheter is present, it is not possible to standardize the amplitude of the external tocodynamometer. The amplitude of the excursions seen in a particular situation is sensitive to the location of the instrument, the tension on the belt, and the adiposity of the individual, among other factors. Contractions that occur before the onset of clinical (true) labor are of relatively mild intensity and can be difficult to distinguish from background "noise." Thus the correlations between the external tracings and actual uterine activity could be substantially lower in the outpatient situation than in the labor room. Improvements in external tocodynamometers or other methods of assessing uterine activity should be sought. A beltless tocodynamometer that is held against the abdominal wall with an adhesive recently has been reported to improve the signal-to-noise ratio, especially during maternal exercise.[6] However, its practicality for routine use at home has not been demonstrated. Changes in other cardiovascular parameters that precede the onset of labor should be studied further.

Difficulty in detecting uterine activity with an external monitor before the onset of labor might be reflected in poor reproducibility in the reading of tracings. Very little information about the reproducibility of either the monitor strips or their interpretation is available. In one carefully standardized study that was conducted with "blind" interpretation of the strips, reinterpretation of 600 1-hour strips by the same individual at a later time yielded exact agreement about the number of contractions per hour 79% of the time and showed agreement within one contraction 95% of the time. These results seem good; however, a number of conferees indicated that reproducibility does not always meet these standards.

It is possible that readers may be better at distinguishing between high-risk and low-risk strips than they are at replicating the number of contractions, especially on strips that have relatively low rates of overall activity. On the other hand, agreement between different individuals might be less than the agreement of one reader with his or her own earlier reading. If the readings cannot be shown to be reliable, their utility in classifying women or in making the early diagnosis of preterm labor would be compromised. The potential use of computer interpretation to attain maximal reproducibility at a much reduced cost is attractive and is probably worthy of developmental effort in the near future.

Several investigators have used external tocodynamometers to monitor the frequency of uterine contractions at various times during the second half of pregnancy.[7-14] Although the extent of standardization of the readings is unclear in several of these reports, there is a surprising amount of consistency in their principal results, which have been as follows: The mean frequency of contractions tends to rise with increasing gestation, except for a minor plateau or dip around 31 to 32 weeks; there is an increase in the frequency of contractions 24 to 48 hours before the onset of labor, whether the labor is preterm or term; at a given gestational age the mean contraction rate of women destined to go into preterm labor is higher than the mean rate of those who are not. Although the overlap between the groups is substantial, a few studies have suggested that this difference could be usefully exploited to identify high-risk women. Further exploration is needed in this area. Additional investigation should attempt, among other things, to clarify to what extent contraction frequency is correlated with other risk factors for preterm labor and to what extent it can provide additional information about the risk of preterm labor that is statistically independent of the usual risk measures.

A number of small, randomized trials have been carried out to assess the efficacy of home uterine activity monitoring in actually preventing preterm birth. In most of these trials very-high risk patients such as those with a twin pregnancy, a uterine anomaly, or a history of preterm delivery have been recruited and instructed about the signs and symptoms of early labor and have been trained in the use of the home monitor. These patients have then monitored themselves at home twice a day (morning and evening) and have transmitted the digitized tracings over the telephone in the evening for central interpretation. The results of the central interpretation and any smptoms during the day are discussed by telephone with a nurse and, if necessary, a third hour of monitoring provides clarification. Patients with atypical symptoms or tracings are referred to their physicians and in many instances are evaluated for preterm labor. An encouraging feature of this strategy has been its modest demand on physician time. The trials usually have shown that fewer than one additional unscheduled visit per pregnancy has resulted from participation in the monitoring program.

Several of these randomized trials have compared the monitoring regimen and accompanying nursing support with a routine standard of care.[1-3] In general, these studies have shown no difference in the frequency of diagnosed preterm labor, a marked increase in the proportion of patients with preterm labor in the monitored group in whom the cervix is considered to be favorable for tocolysis, and a substantial reduction in the monitored group in the frequency of preterm birth. These results appear impressive because the studies used a rigorous randomized design and actually achieved a reduction in preterm births, not merely a difference in cervical status at the time of diagnosis of preterm labor. Similar results have been reported in women whose pregnancies were managed at home after a documented episode of preterm labor earlier in the pregnancy.[15] The finding that the cervix was more often favorable for tocolysis in the intervention group was consistent with expectation and suggested that labor was being diagnosed earlier, which allowed more effective tocolysis.

The main limitations of these trials are as follows: They are of limited size; they have been conducted in a very special group of patients who constitute a modest proportion of the preterm birth problem; investigators failed to show results for the modest number of women randomized to tocodynamometry who failed to use the method; they leave unanswered the question of whether the treatment effect is due to the monitoring per se or whether it might be due to the nursing support or the extra periods of limited activity that may accompany the monitoring process. A less important, unavoidable design problem is that the treatment assignments in these trials cannot be masked. In spite of these limitations the finding that the combined nursing and monitoring program has led to a substantial reduction in preterm births in these very-high-risk women remains a striking, perhaps unprecedented result.

Several investigators have tried to assess the effects of the monitor, as opposed to the effects of nursing support and other aspects of the monitoring protocol, by conducting trials that compared the monitored group with control groups who received equivalent nursing support but no monitoring.[16-20] Although the details of most of these trials are still unpublished, they have not shown a convincing positive effect of monitoring. This may suggest that nursing support alone may be sufficient to produce a beneficial effect in high-risk women. Only one of the trials incorporated a direct comparison between routine care and extra nursing support (with sham monitoring). Whereas the differences found suggested that daily provider-initiated nursing support was effective, the numbers were too small to lead to firm conclusions.[16]

Recommendations for further research

The conferees agreed that the animal and human studies suggesting a change in the frequency and quality of uterine contractile activity that occurs a day or two before labor, the evidence that women destined to go into preterm labor have more contraction activity than women who labor at term, and the prima facie case for efficacy of the monitor in combination with vigorous nursing support all suggest the importance of continuing to investigate the role of monitoring in the prevention of preterm birth. However, the evidence that monitoring per se provided an important contribution either to assessing the risk of preterm labor or to preventing preterm birth was thought by most participants to be less than fully convincing. It appears that additional work is needed both to optimize the ability to conduct home uterine activity monitoring and to demonstrate unequivocally that, in its currrent form, monitoring adds to our ability to prevent preterm birth.

The following studies were suggested:

1. Animal research, and particularly work in nonhuman primates, could be used to explore the conditions and physiologic mechanisms that precipitate or inhibit uterine contractions. This work might provide clues about the best time and conditions for monitoring in high-risk women.

2. Studies in animals (or possibly in humans) needs to be done to produce a better sensor for uterine activity. A detection system that could distinguish between Braxton Hicks contractions and the contractions of early labor would be especially desirable.

3. Studies should be undertaken to assess the sensitivity of external monitors to uterine contractions in women before term who are not in active labor. These evaluations could be done in women with maternal indications for induction and could involve simultaneous internal and external monitoring before active labor is established. Alternatively, the studies might be possible in women who are admitted with ruptured membranes but who are not in labor and in whom delivery is planned within a specified time.

4. Additional work is needed to establish the reproducibility of the reading of tracings obtained from external monitors before labor. An attempt to develop reliable and valid computer interpretations of the tracings should be a high priority. The effect of patient activity and the extent of adiposity on the quality of the tracings need further evaluation. The quality of tracings from different devices also should be formally compared. When patients are monitored repeatedly over a number of days, mathematic approaches to the interpretation of the accumulating data deserve further exploration. Some of this work could be done with tracings that have already been collected.

5. The utility of monitoring contraction frequency in clinic and other outpatient settings as an approach to assessing patient risk status needs further evaluation. These evaluations should be done in contexts in which the quality of the interpretation of the tracings is well documented and the information on other risk factors is available, so that the magnitude of the additional contribution of the monitor information to the prediction of preterm labor or birth can be estimated.

6. A large, randomized trial is needed to verify the effectiveness of the combination of monitoring and nursing support in reducing the incidence of preterm birth in high-risk women. This trial should have several study groups, so that the effect of nursing support without monitoring can be evaluated separately. Some conferees felt that it would also be worthwhile to evaluate the effect of monitoring without intensive nursing support. The question of whether such a trial should be undertaken now or should wait for the completion of some of the projects outlined above was not resolved and would obviously depend in part on the availability of resources.

7. A separate clinical trial might be considered to test the efficacy of monitoring in women who have had an episode of preterm labor and who are at home on a regimen of tocolytic therapy. Additional work on the efficacy of oral tocolytics as compared with subcutaneous infusion of tocolytics might be needed to plan an optimal design for such a trial.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Screening in ovarian cancer

William T. Creasman, MD, and Philip J. DiSaia, MD
Charleston, South Carolina, and Orange, California

Ovarian cancer will affect 20,000 American women this year and some 13,500 will die of the disease. Most patients will have stage III or IV disease at the time of diagnosis. Because ovarian cancer may be initially without symptoms, attempts have been made to develop screening tests that would lead to an early diagnosis. Two tests, serum CA 125 and pelvic ultrasonography, have been suggested by some to be accurate enough to be included in yearly screening for ovarian cancer. Although further testing of these techniques is encouraged, data to date do not justify yearly screening with CA 125 or pelvic ultrasonography in all women. (AM J OBSTET GYNECOL 1991;165:7-10.)

Key words: Ovarian cancer, screening

With the untimely death of Gilda Radner because of ovarian carcinoma, this malignancy has become the cancer of the year. The media have given it considerable publicity with at least two news commentary programs having major segments on this subject. Both featured Gilda Radner's plight. Unfortunately, without her death the public would not have received important information about this cancer. However, awareness alone does not lead to optimal management.

The publicity has emphasized the familial associations and as a result suggested new screening guidelines for this cancer. It has been known for some time that relatives of patients with ovarian cancer have an increased incidence of this cancer although a specific genetic link has not been identified. This appears to be particularly true if two or more family members (first-order relatives) have had ovarian cancer. The familial ovarian cancer registry has accessed 1020 ovarian cancer patients. Obviously this is a highly select group of patients. Recent data from this registry has not been reported in the peer-reviewed literature and only briefly in a 1990 newsletter. Unfortunately, the denominator is unknown. A recent study by Koch et al.[1] evaluated family history of ovarian cancer patients with a case-control study. They identified 197 patients with ovarian cancer diagnosed between Jan. 1, 1984, and March 31, 1986, and 210 control subjects from Alberta, Canada. Because of a population-based cancer registry they were able to include >95% of cancer cases in Alberta and verify the relatives' cancer history. They noted that the family cancer history given by the patient often was inaccurate as to the cancer site. There was a significantly higher incidence of ovarian cancer in the family history of these patients compared with the control group but it is still not very common. This finding may be falsely elevated inasmuch as the control subjects had fewer siblings than did the ovarian cancer patients. Of the 197 cases only 9 (4.6%) had a positive family history of ovarian cancer; only 1 patient with ovarian cancer (0.5%) had more than one relative with ovarian cancer and that patient came from a family of nine sisters. It has been estimated that only 1% to 3% of patients with ovarian cancer fall into this category. Although important for those women who are at risk, family history apparently affects only a small minority of patients.

It has been suggested that all women should have a periodic pelvic examination, pelvic ultrasonographic examination, and CA 125 screening to make sure they do not harbor an occult ovarian cancer. Most would agree that a bimanual rectovaginal examination should be part of the annual physical, although it has been stated that one has to do 10,000 routine examinations to pick up the one early ovarian cancer. That is one of the problems with this cancer—the incidence is relatively low with no known preinvasive lesion. There are approximately 20,000 new ovarian cancers each year compared with approximately 150,000 breast cancers. For a screening test to be effective there needs to be an appreciable prevalence, an identifiable preinvasive lesion, and an effective screening test with high sensitivity and specificity. With that caveat in mind, we examined ultrasonography and CA 125 as screening tools.

CA 125

The use of CA 125 as a screening technique is being evaluated in Stockholm. In 1990 a preliminary report was published.[2] A total of 1082 women aged 40 years or older had serum CA 125 levels determined. Thirty-six (3.3%) had levels >35 U/ml and 11 (1.0%) had levels >65 U/ml. Although several of these women continued

to have elevated CA 125 levels, only two had a doubling of these levels and in only one was this increase sustained. Twenty-one months after the initial elevated CA 125 levels (35.3 U/ml) were recorded and 15 months after the first doubling (69.7 U/ml) a stage III mixed mesodermal ovarian cancer was diagnosed.[3] With the use of the "doubling rule" the specificity of the assay for one ovarian sarcoma was 99.9%. The specificity was 100% for a "sustained increase rule" (positive for the doubling rule, the levels continue to rise progressively for an additional period of time). The predictive positive and negative values would have been lower with the initial values. The yearly incidence of ovarian cancer in Sweden in the age group tested is about 30/100,000 population and perhaps an additional 30 cases prevalent but not clinically manifested. If prevalence of the disease is 30 to 60 cases per 100,000 then even with a specificity of 99.5% only 6% to 11% of all women with elevated CA 125 levels would actually be expected to have cancer even if the sensitivity was 100%. A subsequent abstract[3] updated this experience. A total of 5550 women were measured annually. Among 175 women with elevated CA 125 levels, six ovarian cancers were detected clinically or ultrasonographically. Four of the six patients had stage IIB or III ovarian cancers. The authors stated "A prospective controlled trial will be required to determine whether such screening reduces mortality."

A retrospective study by Zurawski et al.[4] from Norway evaluated CA 125 from the JANUS serum bank, which is a repository of specimens collected since 1973 from more than 100,000 persons. The authors were able to identify 105 patients who had banked serum and in whom an ovarian malignancy subsequently developed. They compared these results with 320 matched control subjects. The authors identified 12 patients who had blood drawn ≤18 months before the diagnosis. One of the patients had a tumor of low malignancy potential. Only four of these 12 had CA 125 levels >35 U/ml. Three of these had localized disease. One patient had a diagnosis made 1 month after the blood was drawn and she had disseminated disease. Whether the three patients with localized disease could have had the diagnosis established at an earlier time because of the screening for CA 125 is obviously unknown. No data are given as to the subsequent course of these three patients. In another study, Jacobs et al.[5] tested 1010 postmenopausal volunteers with CA 125. One case of ovarian cancer was detected by screening; the CA 125 level was 32 U/ml. No other patient has presented clinically after about 2 years of follow-up. With the use of a 30 U/ml cutoff, the detection rate was 100%, the false-positive rate was 3%, and the odds of being affected given a positive result (the ratio of the number of true-positives to the number of false positives) was 1:30.

The use of CA 125 has been evaluated in an attempt to distinguish benign from malignant masses in patients with known pelvic masses. Malkasian[6] evaluated CA 125 levels in 158 patients with palpable pelvic masses. Sixty-eight were found to have cancer with the other 90 benign. In the latter group 72 (80%) had CA 125 levels <35 U/ml. In the 68 patients with cancer, 21% had CA 125 levels <35 U/ml and 17 (25%) had levels <65 U/ml. If the CA 125 level of 65 U/ml was the cutoff value, the sensitivity was 60% and specificity was 89% in the premenopausal group and 78% and 97%, respectively, in the postmenopausal group. Patsner and Mann[7] evaluated 250 consecutive patients with pelvic masses. Of those with benign disease, 16/74 (21%) who were premenopausal had CA 125 levels >35 U/ml. In the postmenopausal patients with benign disease 9/48 (18%) had elevated CA 125 levels. Of those with malignant gynecologic cancers, 63% of the premenopausal patients and 77% of the postmenopausal patients had elevated CA 125 levels. Sensitivity for CA 125 was 0.65 and 0.77 for premenopausal and postmenopausal patients, respectively; specificity was 0.78 and 0.81, respectively. Positive predicted value was 0.67 in the premenopausal patients and 0.87 in the postmenopausal patients, whereas the negative predictive value was 0.77 and 0.68, respectively.

Finkler et al.[8] correlated CA 125 levels in patients with adnexal masses singularly and in combination with clinical impression as well as with initial and review ultrasonography. They evaluated 102 consecutive patients with adnexal masses. A clinical impression was determined preoperatively by the examiner as to whether a mass was thought to be benign or malignant. A pelvic ultrasonographic examination was performed and impression of benign or malignant was given by the initial reviewer. Ultrasonographic scans were then reviewed by the "expert" who had very strict criteria for the designation of malignancy. Eighteen of 70 (24%) of the premenopausal patients and 19 of 32 (59%) of the postmenopausal patients had a malignancy. In the premenopausal patients the predictive positive and negative value for CA 125 was 36% and 82%, respectively, which was comparable to the clinical evaluation and the initial ultrasonographic review. In the postmenopausal patients the predictive positive and negative values for the CA 125 was 94% and 80%, respectively. Predictive positive value of the clinical and initial ultrasonographic review were similar; however, the CA 125 did have a better predictive negative value than did the clinical or initial ultrasonographic review.

An interesting study of 4000 volunteers has been reported from Kings College in London.[9] The patients were older than 44 years of age and were postmenopausal. They underwent a vaginal examination and a CA 125 evaluation. Those persons with an elevated CA 125 level (>30 U/ml) or those who had abnormal examination results were recalled for abdominal real-time ultrasonography. If the ultrasonographic examination revealed an ovarian enlargement, patients were further investigated surgically. It was noted that in 3839 patients the CA 125 screening and pelvic examination results were normal and an ultrasonographic examination was not performed. In the second group all 69 patients had elevated CA 125 levels; however, the pelvic examination results were normal. Four patients had abnormal ultrasonographic results and at the time of surgery no cancers were noted. The third group of patients comprised persons who had abnormal pelvic examination results and normal CA 125 levels. In this group of 91 women, 19 had abnormal ultrasonographic results and in the 19 who underwent surgery no cancers were noted. In the last group, there was only one patient who had an elevated CA 125 level (32 U/ml) and abnormal pelvic examination and ultrasonographic results. She was found to have stage IA clear cell carcinoma of the ovary. None of the other patients in the study has had documented ovarian cancer after a minimum follow-up of 12 months. In this study the CA 125 level and the pelvic examinations were both highly specific (97% and 97.3%, respectively). If a patient had an elevated CA 125 level and either abnormal pelvic or ultrasonographic examination results, specificity was 100%. Finkler[6] noted in his study that in the postmenopausal patient with an abnormal CA 125 level that if either the pelvic or ultrasonographic examination was positive, the positive predictive value was 100%.

Ultrasonography

A study from England[10] has been reported in which the value of ultrasonography in the screening procedure for early ovarian carcinoma was evaluated. Almost 5500 women were self-referred and underwent a first screening. Ninety percent of these had a second screening and three fourths had a third screen. Eventually 5479 women were monitored over 8 years with 14,594 screenings (15,977 scans) and 29,140 ovaries examined. The median interval between the first and second screening was 614 days and 564 days between the second and third screening. These women were aged 45 years or more and could be either premenopausal or postmenopausal. The authors of this study are considered to be leading authorities in ultrasonography for obstetrics and gynecology worldwide. They use three criteria for designation of a positive scan: ovarian morphology (hyperecogenicity or hypoecogenicity), outline (irregular), or volume (>20 ml). The ovaries had to be identified to give a negative or positive scan. Women with normal scan results were then asked to return 1 year later. Those with an abnormal result were rescanned after 3 to 8 weeks to exclude any transient change in morphology or size. A total of 14,594 patients were screened from one to three times. A total of 654 scans were positive initially but became negative on rescanning; 338 scans were positive both on the initial and the rescan. A total of 326 women (from 338 scans) underwent exploratory laparotomy. Five patients had primary ovarian cancer; three were classified as borderline. All the primary cancers were stage IA or IB. All these patients are alive at least 2 years after surgery. Three of the primary cancers were detected at second screening at 16, 18, and 22 months after the first screening. In addition, there were four patients with metastatic ovarian cancers. The authors stated that they were unable to identify any morphologic characteristic or condition that could be used to differentiate between benign and early malignant tumors. The overall specificity of the screening procedure was 97.7% and predictive value for positive result was 1.5%. Therefore the odds of having a primary ovarian cancer in a patient with a positive result was only 1:67, indicating that 66 of the 67 patients who underwent exploratory laparotomy had no evidence of a borderline or invasive primary cancer. There was an additional 186 patients who declined surgical procedures or became nonattenders. Because cancer had not become apparent at least clinically in this latter group of patients, the odds of positive finding would decrease even more than the 1:67 the authors actually noted. These authors are proceeding to a very large screening protocol to determine whether ultrasonography is a useful screening tool and to determine cost effectiveness. Obviously the benefit of using this modality as a screen for ovarian cancer has not been proved and further evaluation may be justified.

Prevention of ovarian cancer

It should be remembered that ovarian cancer can be markedly reduced with the use of oral contraceptives. Fourteen studies in the literature all show a decrease risk. After 4 years of use, there is a 50% reduction and with 7 or more years there is a 60% to 80% reduction in ovarian cancer. Obviously such prevention would appear to be more effective in lowering the incidence and death rates of this cancer than currently available diagnostic tests of our current therapy.

Comment

In the small group (<5%) of high-risk patients, a CA 125 and pelvic ultrasonographic screening may be periodically justified. There is no data to support this action; however, it may be acceptable if for no other reason that to reassure these patients.

It is estimated that there are more than 43,000,000 women in the United States aged 45 years or older. A common cost of nonobstetric diagnostic pelvic ultrasonographic examination is $275.00. A CA 125 screen-

Predictive value of early embryonic cardiac activity for pregnancy outcome

Erik H. Merchiers, MD, Marc Dhont, MD, PhD, Paul A. De Sutter, MD,
Cathy J. Beghin, MD, and Dirk A. Vandekerckhove, MD, PhD
Ghent, Belgium

The biologic variation of the embryonic heart rate was investigated by transvaginal ultrasonography during the first trimester of normal ($n = 141$) and abnormal ($n = 29$) pregnancies, and the predictive value of a repeatedly diagnosed slow heart rate for pregnancy outcome was determined. The mean heart rate increased from 82 ± 10.3 beats/min at 5 weeks' gestation to 156 ± 9.6 beats/min at 9 weeks. A single observation of an abnormally slow heart rate did not necessarily predict subsequent embryonic death. However, a continued decline in embryonic heart activity, observed within a few days' interval, was always associated with a first-trimester abortion. (AM J OBSTET GYNECOL 1991;165:11-4.)

Key words: Fetal heart rate, first-trimester abortion, transvaginal ultrasonography

The earliest proof of a viable pregnancy is obtained when cardiac activity of the embryo can be observed. High-frequency vaginal transducers have improved embryonic imaging in early pregnancy and have facilitated the very early detection of cardiac activity. Several investigators[1-3] have reported a gradual increase in embryonic heart rate as detected by ultrasonography starting in the fifth week of pregnancy. Hence, a heartbeat frequency hovering around 100 beats/min may be a physiologic phenomenon in early pregnancy.[2,3] There is evidence, however, that an abnormally slow heartbeat is associated with impending embryonic death,[1] but the predictive value of embryonic heartbeat frequency for the evolution of early pregnancy is still unknown. Therefore it was the aim of this study to define the evolution and the biologic variation of early embryonic heart rate between the fifth and twelfth weeks of pregnancy and to correlate abnormally slow heart rates with pregnancy outcome.

Material and methods

This study was performed over a 6-month period on 170 pregnancies (fifth through twelfth weeks, 552 observations) examined in our ultrasonography department. Patients were referred from either our outpatient or infertility clinic. Of these 170 patients, 146 conceived spontaneously and 24 became pregnant after gamete intrafallopian transfer ($n = 5$), in vitro fertilization and embryo transfer ($n = 16$), or zygote intrafallopian transfer ($n = 3$). Patients were included only when follow-up beyond the first trimester of pregnancy was available and when gestational age was accurately determined by basal body temperature chart, luteinizing hormone surge, or date of ovum pickup. The heart rate was measured by counting heartbeats several times for periods of 15 seconds, averaging, and multiplying by four. All scans were done by the same observer using a 5.0 or 7.5 MHz ATL (Ultramark) vaginal transducer.

Results

Of the 170 patients recruited in this study, 141 (14 in vitro fertilization, 5 gamete intrafallopian transfer, 2 zygote intrafallopian transfer) were pregnant, and 29 experienced a miscarriage before week 12. One of those miscarriages was ultrasonographically and histologically diagnosed as hydatidiform mole. In the uncomplicated pregnancies fetal cardiac activity could be detected as early as 5 weeks 3 days (20/24 observations). Between 5 weeks 3 days and 6 weeks cardiac activity was registered in 36 of 42 embryos. Cardiac activity was always detected in the uncomplicated pregnancies from 6 weeks 1 day on (345 observations). Although the em-

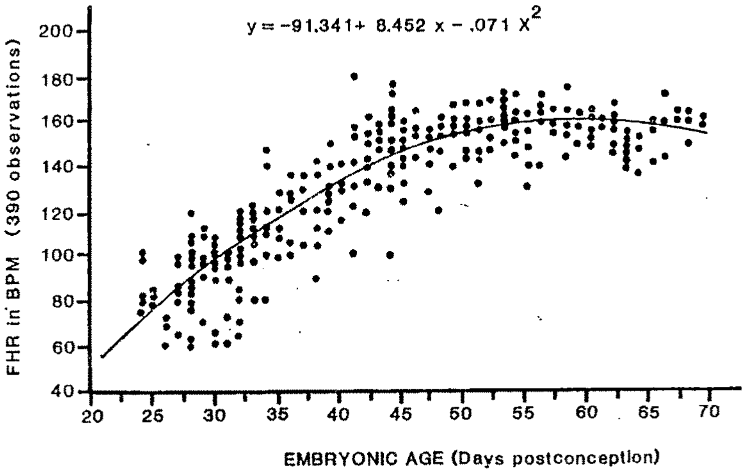

Fig. 1. Embryonic heart rates in 141 normal first-trimester pregnancies (390 observations).

Table I. Mean embryonic heart rates in first trimester of pregnancy (141 normal pregnancies)

Gestational age (wk)	*No. of examinations*	*FHR (beats/min, mean ± SD)*
5	47	82.41 ± 10.34
6	77	95.83 ± 18.85
7	66	125.35 ± 18.30
8	65	146.68 ± 15.13
9	56	156.23 ± 9.63
10	40	157.12 ± 8.13
11	25	153.68 ± 8.79
12	25	152.56 ± 9.06

Spearman rank correlation: $R = 0.80$, $p < 0.001$.

bryonic heart rate varied considerably between the sixth and twelfth weeks of gestation, ranging from 60 to 170 beats/min, the mean fetal heart rate (FHR) increased significantly from 82 beats/min (fifth week) to 156 beats/min (ninth week) (Table I, Fig. 1).

Not included in these calculations is the extremely low cardiac activity we observed on a single occasion at 7 weeks' gestation in an otherwise uneventful pregnancy. A FHR of 48 beats/min persisted for >5 minutes. We recorded the entire observation period on videotape. The maternal radial pulse at that moment was 80 beats/min. This disquieting image disappeared spontaneously and could not be reproduced on reinsertion of the vaginal probe a few minutes later.

An embryo could be visualized in 26 of 29 cases of subsequent first-trimester abortion. In 10 of these cases heart activity was never detected, whereas in the remaining 16 heart activity was recorded on several consecutive occasions with an interval of 3 to 4 days. In nine of these 16 cases the maximum FHR did not exceed 100 beats/min, and in 10 we recorded a gradually declining heart activity at repeated scans with an interval of 2 to 3 days, until heart activity could no longer be observed (Fig. 2). The heart rates of what we called "dying embryos" ranged from 52 to 100 beats/min. A heartbeat was always detected after 6 weeks 1 day in the normal pregnancies; therefore an absent ($n = 10$) or delayed ($n = 5$) appearance of the FHR from that moment on invariably predicted abortion (sensitivity, 100%; specificity, 100%). The specificity, sensitivity, and predictive value for different cutoff levels of FHR at week 7 are given in Table II.

Comment

The cardiovascular system is the first system to function in the embryo.[4] During embryonic development the FHR develops from splanchnopleuric mesoderm that forms a horseshoe-shaped area in the anterior part of the embryonic disk, part of the secondary yolk sac wall. In this region two midline endothelial heart tubes form (18 to 19 days after conception) and fuse to form a single heart tube (22 days after conception; 5 weeks 1 day of pregnancy). At that very moment the heart begins to contract and has a peristaltic wave motion.[4] Before 22 days after conception it is impossible to detect cardiac activity by ultrasonography. The atrium and ventricle move blood in an ebb-and-flow fashion. By the sixth week of pregnancy the flow becomes unidirectional and cardiac contractions have become coordinated. Between 5 and 6 weeks' gestation, the body folds constrict the yolk sac, and the part incorporated into the embryo forms the epithelium of the gut tube.[4] The remainder of the yolk sac (visible ultrasonographically) is adjacent to the embryo and connected to it by the yolk stalk immediately caudal to the fetal heart bulge, just before and at 6 weeks' gestation. Because of this relationship, we used the yolk sac as an anatomic landmark when searching for early embryonic heart activity. At 6 weeks the embryo is approximately 4 mm.

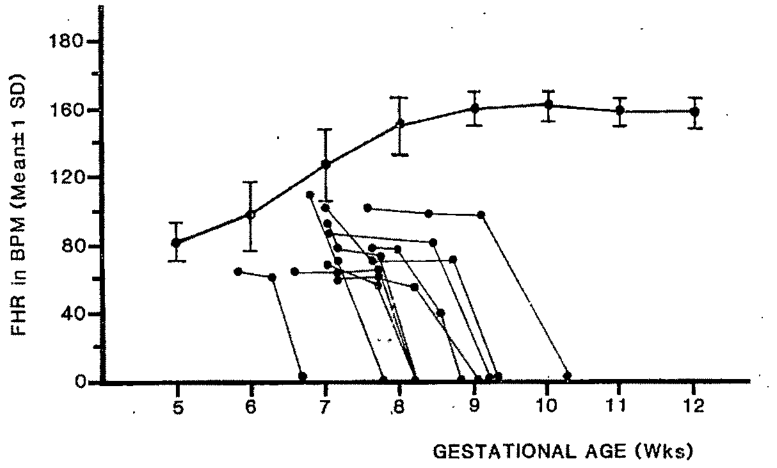

Fig. 2. Mean FHR (± 1 SD) as a function of gestational age in 141 normal pregnancies. Upward trend of normal heart rates between 5 and 9 weeks is demonstrated. On this graph individual *solid lines* represent consecutive FHR registration of dying embryos, which are characterized by a "vanishing heart activity" pattern.

Table II. Operating characteristics at different FHR cutoffs at week 7

FHR (beats/min)	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*
120	96	62	50	97
100	88	88	75	95
80	71	98	94	89

Barry[5,6] studied the developing chick heart and demonstrated that the initial heart rate was very slow under physiologic conditions. The rate increased as the atrium differentiated and assumed a pacemaker function. Several earlier ultrasonographic studies regarding embryonic heart rates demonstrated an upward trend in heart rate early in the first trimester.[1-3,7,8] The pioneer study of Robinson and Shaw-Dunn[8] of the embryonic heart rate after the sixth week of pregnancy revealed that the rate increased from 123 beats/min at 45 days to a peak of 177 beats/min at 15 weeks. Shenker et al.[3] described heart rates of 90 beats/min at 6 weeks and 124 at 7 weeks. The biologic significance of abnormally slow embryonic heart rate has not yet been extensively investigated. Fine et al.[9] described a gradual increase in normal heart rates between 6 and 9 weeks but also reported one case of bradycardia resulting in spontaneous abortion. Hertzberg et al.,[2] however, emphasize that slower heart rates are normal in early pregnancy and warn against their misinterpretation as an abnormal finding or their confounding with maternal pulsations. In a series of 56 viable pregnancies, Laboda et al.[1] found normal first-trimester FHRs to rise from an average of 100 beats/min at 5 to 6 weeks to 140 beats/min at 8 to 9 weeks. None of the ongoing pregnancies had an FHR <90 beats/min. According to these investigators, an FHR <85 beats/min invariably was associated with a poor prognosis. The results of our study confirm the gradual increase of fetal heart rate between 5 and 9 weeks' gestation. Fetal cardiac activity on vaginal ultrasonography is a reassuring sign, but there is still a risk of early pregnancy loss. Although abnormally slow cardiac activity may be associated indeed with impending embryonic death, the predictive value of a single observation at different cutoff levels (e.g., 100 beats/min) is too low to be of any clinical value (Table II). It can provide a warning signal and an indication to perform a repeat scan at a later date. If the FHR declines further on subsequent scans, eventual embryonic death is highly probable. In our series an overall sensitivity of 83.4% and specificity of 97.9%

Table III. Operating characteristics for decreasing FHR pattern and cutoff level of 100 beats/min as predictor of spontaneous abortion between weeks 5 and 10 of pregnancy

True positive: 10	False positive: 3
True negative: 139	False negative: 2
Specificity: 97.9%	Sensitivity: 83.4%
Positive predictive value: 76.9%	
Negative predictive value: 98.6%	

was noted when a cutoff value of 100 beats/min was combined with a declining FHR (Table III).

If we focus on the same criteria in the seventh week of pregnancy, sensitivity and positive predictive value increase to 90.8% and 83.4%, respectively. On the basis of these findings, the seventh week of pregnancy seems to be the most appropriate time to predict the outcome of early pregnancy with a combination of declining FHR and FHR cutoff at 100 beats/min.

It can only be speculated whether the association between impending embryonic death and slow heart rate is a general manifestation of poor embryonic development or, at least in some cases, results from a primary cardiac defect. Shenker et al.[3] ascribe the slower heart rates in early pregnancy to the immaturity of the sinoatrial node or to slower intrinsic atrial pacemaker activity. On the other hand, embryonic bradycardia may reflect idioventricular rates in an abnormally developing heart, or it may be due to an arrest in the development of the conduction system.

The single case of extreme but transient bradycardia (48 beats/min) in an eventually normal pregnancy, however, illustrates that physiologic mechanisms also can play a role. In this patient the uterus was extremely anteverted and the bladder was empty. When the ultrasonographic transducer is pressed too firmly on the vaginal and thus on the uterine wall, an increase in intrauterine pressure results; if so, the increased intrauterine pressure is transmitted throughout the intrauterine cavity and on all parts of the embryo, including the umbilical vessels. As a result, a primitive efferent vasodepressor response could occur through the vagal center. This phenomenon also was described by Mendoza et al.,[10] who induced fetal bradycardia in midpregnancy by applying pressure to the maternal abdomen during ultrasonographic examination.

In conclusion, use of the transvaginal probe has made it possible to detect embryonic heart activity as early as 5 weeks 3 days of pregnancy. A gradual heart rate increase from 82 beats/min at 5 weeks to 157 beats/min at 10 weeks is a physiologic phenomenon related to the development of the embryonic heart and conduction system. Hence the single observation of a slow FHR has no clinically significant predictive value for the outcome of early pregnancy. On the contrary, a repeatedly detected abnormally slow heart rate signals delayed and poor embryonic development or an abnormally developing heart and predicts subsequent miscarriage. In rare cases, however, this pattern may be the manifestation of a defective heart conduction system.

Double jeopardy: Twin infant mortality in the United States, 1983 and 1984

Mary Glenn Fowler, MD, MPH,[a] Joel C. Kleinman, PhD,[a] John L. Kiely, PhD,[a] and Samuel S. Kessel, MD, MPH[b]

Hyattsville and Rockville, Maryland

The United States Linked Birth/Infant Death Data Sets: 1983 and 1984 Birth Cohorts from the National Center for Health Statistics were used to identify maternal and infant characteristics related to twin infant mortality; 41,554 white and 10,062 black live-born matched twin pairs were evaluated. Twin birth weight distribution was skewed with 48% of white and 63% of black twins born weighing <2500 gm. Overall infant mortality rates were 47.1 and 79.3 deaths per 1000 live births for white and black twins, respectively (five times the rates for singletons). Three fourths of deaths were among twins weighing <1500 gm. White like-gender twins had about twice the risk of both twins dying compared with unlike-gender twins. Likewise, white twin pairs with >25% birth weight disparity had a 40% to 80% increased risk of both twins dying, compared with twins whose weights were within 10% of each other. Twins born to high-risk women (on the basis of demographic factors) were twice as likely to die as twins born to low-risk women. Thus strategies to decrease twin infant mortality must address both maternal and infant risk factors. (AM J OBSTET GYNECOL 1991;165:15-22.)

Key words: Twins, infant mortality, risk factors

From conception, human twinning is a high-risk event. On the basis of ultrasonographic studies, one fetus vanishes by the end of the first trimester in approximately 20% of twin pregnancies.[1] Problems later in pregnancy include high rates of toxemia and increased risk of fetal death, premature delivery, and intrauterine growth retardation, when compared with singleton pregnancies.[2] Thus, although twins represent only 2% of live births, they account for approximately 10% of perinatal deaths.[3] In addition, infant death rates among twins are estimated to be four to 10 times those of singleton births.[4-6]

In spite of the documented risk of increased infant mortality among twins, data on factors associated with this increased mortality are inconsistent. Previous research has often been limited by small sample size and lack of generalizability of the study populations. For example, some researchers have shown higher neonatal mortality for second-born twins,[7, 8] but others[2, 9] have not. Findings on mortality rates of like-gender versus unlike-gender twin pairs also have varied, although the majority of studies[4, 9, 10] indicate that monozygotic twins (particularly monoamniotic twins)[11] have higher mortality rates than dizygotic twins.

Likewise, although congenital anomalies are known to be a leading cause of infant deaths among twins, studies disagree regarding rates of congenital anomalies among twins compared with singletons[1, 4] or differences in congenital anomaly rates among like- versus unlike-gender twin pairs.[1, 4, 7]

In addition to these infant factors, increased infant mortality among twins probably is also related to the limited adaptability of the human uterus to accommodate multiple fetuses.[7] Furthermore, twinning is associated with other recognized maternal risk factors for infant mortality, such as advanced maternal age and parity and black ethnicity.[2]

In view of the limitations of previous research on twin infant mortality, this study of national vital statistics was undertaken to evaluate factors related to infant mortality among black and white twins. The Linked Birth/Infant Death Data Sets: 1983 and 1984 Birth Cohorts from the National Center For Health Statistics (NCHS), representing the cohort of all live births in the United States in 1983 and 1984 and any subsequent infant deaths among the cohort, were used for the analyses. Black and white twins were studied separately. Infant mortality was chosen as the outcome for the analyses, since with neonatal intensive care the timing of deaths related to perinatal problems often extends beyond the neonatal period.

Methods

Data were obtained from the Linked Birth/Infant Death Data Sets: 1983 and 1984 Birth Cohorts. Infant death records from 1983 or 1984 NCHS mortality files were linked with 1983 NCHS birth records, and infant death records for 1984 and 1985 were linked with 1984 United States birth records. The data files include birth and death records of United States residents that occurred in the United States but exclude births and deaths of United States residents occurring outside the United States.

The focus of several of the analyses presented here was on twin pair characteristics, rather than on individual twins. Thus every effort was made to match cotwins from the same pregnancy. Live births in twin deliveries were matched with respect to county and state of birth, maternal race, age, county and state of residence, prior live births, month prenatal care began, education, and martial status as well as father's race, age, and education, to identify twin pairs. Of the 135,051 twins on the 1983 and 1984 birth files, 105,576 (78%) were successfully paired. Of the remaining unmatched 29,475 twins, 1939 were omitted because more than two records had identical matching variables and 27,536 had no matching birth. Of the latter, 11,458 were born in one of four states (Arizona, California, Delaware, Georgia) or Washington, D.C., which included only a 50% sample of births (for which no match of twin pairs would be expected). The primary reasons for failure to find a match for the remaining 16,078 twins included inconsistent birth order data and the possibility of fetal death of the other member of the twin pair. The infant mortality rates that were based on the matched pair data file were 1.1% lower for white and 1.2% lower for black twins than the rates that were based on the unmatched twins. Thus the omission of the unmatched twins does not appear to introduce any substantial bias.

The analyses presented here are based on the 41,544 white and 10,062 black twin pregnancies in which liveborn twins were successfully paired. Some analyses, including birth weight–specific, gender and birth order mortality rates and specific cause of death, were calculated from a data file that included all twin pairs and a selected number of demographic variables. Other analyses (infant mortality rates in relation to maternal risk factors and infant pair characteristics) used a more detailed file, which included all twins pairs in which either or both members died and a 10% sample of pairs in which both members survived.

Infant mortality rates by individual twin infant factors including gender, birth order (twin A vs twin B), and birth weight were calculated for blacks and whites. The relationship of gestation to infant mortality was not presented because of the questionable reliability of last menstrual period–based gestation data.[12]

The relationship of twin pair characteristics to infant twin mortality was assessed for the separate outcomes in which either member or both members of a twin pair died. Twin pair characteristics evaluated were gender pair differences (unlike-gender pairs vs like-gender male pairs or like-gender female pairs) and birth weight differentials between the twin pair members. With respect to gender pair differences, all unlike-gender pairs were obviously dizygotic. However, from the available data, monozygotic twins could not be identified from among the like-gender twin pairs. Birth weight differentials were categorized into five intervals, according to the difference between the twins' weights in grams relative to the average weight of the pair:

The difference (A − B) was >25% of the average weight of the pair (A 25% >B).
The difference (A − B) was 10% to 25% of the average weight of the pair (A 10% to 25% >B).
The difference (A − B) was within 10% of the average weight of the pair (A = B).
The difference (B − A) was 10% to 25% of the average weight of the pair (A 10% to 25% <B).
The difference (B − A) was >25% of the average weight of the pair (A 25% <B).

Summary levels of maternal demographic risk (low, moderate, or high) that had been developed for singletons[13] were analyzed in relation to twin infant mortality. Births with education not stated (primarily births in Texas and Washington where education is not on the birth certificate) were excluded from these analyses. The low-risk group consisted of married primiparous women 20 to 29 years old and low-parity (one prior birth to women <25 years old or two or fewer prior births to women ≥25 years old) multiparous women who were ≥20 years old with ≥13 years of education. The high-risk group consisted of unmarried teenagers, primiparous women ≥30 years old, and high-parity (two or more prior births to women <25 years old or three or more prior births to women ≥25 years old) multiparous women with <12 years of education. The moderate-risk group included all other combinations of maternal characteristics.

Twin infant mortality rates, risk ratios, and confidence limits were computed for black and white twins separately, according to individual twin characteristics (sex and birth order) and twin pair characteristics (like- vs unlike-gender and birth weight differential) for two pair outcomes: both twins died and either twin died. These analyses were done with the BMDP statistical programs.[14]

Cause-specific mortality. Cause-specific infant mortality rates per 100,000 live births were calculated for firstborn and second-born twins with the three-digit and four-digit ICD-9 codes recorded for cause of death, according to the ninth revision of the International Classification of Diseases.[15] From these mortality rates

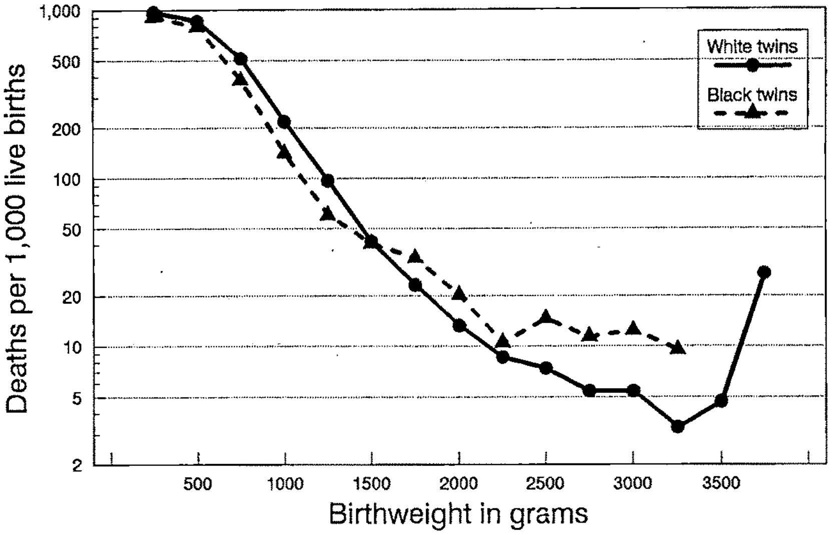

Fig. 1. Birth weight–specific infant mortality rates for black and white twins, from Linked Birth/Infant Death Data Sets: 1983 and 1984 Birth Cohorts for the United States.

cause-specific relative risks for second-born compared with firstborn twins were generated to clarify previous research regarding cause-specific mortality risks of second-born compared with firstborn twins. An obvious caveat regarding these death certificate data is that the information is less accurate than research data obtained directly from autopsy findings; however, these are the only national data regarding specific causes of death that were available to us from the linked files.

Preliminary analyses revealed that the category *Newborns Affected by Maternal Complications of Pregnancy* (ICD-761), which includes *Multiple Pregnancy* as a subcode, was the second most frequently listed cause of death among twins. This was due to a coding rule requiring the choice of ICD-761.5 *(Multiple Pregnancy)* as the underlying cause of twin death instead of ICD-765 *(Short Gestation and Unspecified Low Birthweight)*, even if the physician had listed ICD-765 as the underlying cause. To establish a more meaningful assessment of ICD-761 and ICD-765 among twins, deaths for which ICD-761.5 *(Multiple Pregnancy)* was recorded as the underlying cause of death were recoded to ICD-765 *(Short Gestation and Unspecified Low Birthweight)* if the latter code was listed as one of the multiple causes of death.

Results

The Linked Birth/Infant Death Data Sets from 1983 and 1984 included 41,554 white and 10,062 black twin pairs in which both members were born alive. Approximately two thirds of the twin pairs were like-gender pairs (30,191 white and 6572 black pairs).

Approximately one half of white twin births and two thirds of black twin births were low birth weight (LBW), (<2500 gm), whereas 9% of white and 16% of black twin births were in the very-low-birth-weight (VLBW, <2500 gm) category. This contrasts with national data regarding singleton births in which only about 5% of white and 11% of black singleton births occurred in the LBW category; only 1% of white and 2% of black singleton births were in the VLBW category.[3] Firstborn twins were slightly heavier than second-born twins. Among whites, firstborn twins included 46.5% weighing <2500 gm and 8.5% <1500 gm, compared with 48.7% and 8.7%, respectively, for second-born twins. Among blacks, the differentials were similar: 61.1% <2500 gm and 15.4% <1500 gm for firstborn twins compared with 63.2% and 16.0% for second-born twins.

Infant mortality. There were 3911 white and 1595 black infant twin deaths. Overall infant mortality rates for white and black twins were 47.1 and 79.3 per thousand live births, respectively. These rates are approximately five times those for white and black singletons. However, the black/white mortality ratio is slightly lower for twins (1.68) than for singletons (2.03).[3]

Three fourths of infant twin deaths for both races occurred in the VLBW category. As with singleton births, there was a crossover in the birth weight–specific mortality rates by race. Black twins had a relative survival advantage in the VLBW range and a survival disadvantage above this range (Fig. 1). The lowest mortality rate for white twins was at 3250 gm (3.2 deaths per thousand live births) and rose sharply above 3500 gm. Among black twins, the lowest mortality rates were among those who weighed ≥2250 gm, with <12 deaths per thousand live births. Above 3000 gm the small numbers of black twins precluded accurate calculation of mortality rates on the basis of this matched twin pair data set. However, previous data from 1983 unpaired twin files revealed an increase in mortality above 3250

gm, indicating a similar pattern to white twins at the highest birth weights.[3]

With respect to timing of death, four fifths of white and three fourths of black twins died in the neonatal period (0 to 27 days). In the neonatal period a slightly higher percentage of infant deaths occurred among twin members of like-gender pairs than among twins of unlike-gender pairs (83% vs 78% among whites and 78% vs 71% among blacks).

Infant mortality rates by birth-order status (firstborn or second-born) and gender are presented in Table I. There were only minimal differences in mortality rates for firstborn and second-born twins. Among both races, male twins had 20% to 30% higher mortality rates than female twins.

Mortality rates with respect to twin pair characteristics are presented in Table II. Note that in this table and in Table III rates are expressed per 1000 twin

High	1,637	78.2	2.2	1.5-3.2	138.7	2.0	1.5-2.6

*The low-risk group consisted of married primiparous women 20 to 29 years of age and of low parity (one prior birth to women <25 years old or two or fewer prior births to women ≥25 years old) and multiparous women who were ≥20 years old with ≥13 years of education. The high-risk group consisted of unmarried teenagers, primiparous ≥30 years old and of high parity (two or more prior births to women <25 years old or three or more prior births to women ≥25 years old), and multiparous women with <12 years of education. The moderate-risk group included all other combinations of maternal characteristics.

pregnancies, rather than per 1000 live births, in order to present the risks of both and of either (i.e., one or both) member of the twin pair dying. Among whites, like-gender pairs were at highest risk of death, compared with unlike-gender pairs, particularly for death of both twin members. White like-gender male twins had a 60% increased risk of either twin member dying and a 120% increased risk of both twin members dying, whereas white like-gender female pairs had a 20% increased risk of either twin member dying and a 70% increased risk of both members dying. Much less difference in mortality rates was noted for black like- versus unlike-gender pairs, although like-gender black male pairs did have a 30% increased risk of both members of the pair dying, compared with unlike-gender pairs. In contrast, black like-gender female pairs appeared to have a slight survival advantage, compared with unlike-gender pairs. These gender-pair mortality findings among whites may be partly related to birth weight distribution: A larger proportion of white like-gender versus unlike-gender twins were VLBW (9% vs 7%) and LBW (49% vs 43%). Among blacks, in contrast, there were almost no differences in percentages of like- versus unlike-gender VLBW twins (16% vs 16%) or LBW twins (63% vs 62%).

Assessment of infant mortality rates for either twin dying or both twin members dying in relation to birth weight differentials between the pair revealed a U-shaped curve among whites with excess mortality at the extremes (twin A >25% B or twin A <25% twin B) when compared with twin pairs whose members' birth weights were less disparate (Fig. 2). Among blacks, however, the excess mortality was evident only in the extreme at which twin A weighed more than twin B. (It is also of interest that the black/white mortality differential is considerably smaller at these extremes than in the less extreme weight difference categories.)

Twin infant mortality rates and risk ratios that are based on levels of maternal demographic risk levels (low, moderate, or high) are presented in Table III. Among whites, 30% of the twin pregnancies were to low-risk and 3% to high-risk mothers. Among blacks, 11% were to low-risk and 18% to high-risk mothers. The relative risks for infant twins born to moderate-risk mothers were 1.1 to 1.2 for whites and 1.2 to 1.4 for blacks. For high-risk mothers of both races the risk of infant death was similar: Infant twins born to white high-risk women had 2.0 to 2.1 times the risk of infant death, and twin infants born to black high-risk women had 2.0 to 2.2 times the risk of infant death, when compared with infants born to low-risk women.

Cause-specific mortality. Cause-specific mortality for firstborn and second-born twins was evaluated according to the underlying cause of death (ICD-9) recorded on the infant death certificate. The leading causes of twin mortality were neonatal deaths related to LBW. Among white twins, *Respiratory Distress Syndrome* (ICD-769) was the underlying cause for 22% of infant deaths; this, combined with *Other Respiratory Conditions of the Fetus and Newborn* (ICD-770) and *Disorders of Short Gestation and Unspecified Low Birthweight* (ICD-765), accounted for 53% of twin deaths. Among black twins, *Respiratory Distress Syndrome* was the underlying cause of death for 15% of infants, and, combined with *Other Respiratory Conditions of the Fetus and Newborn* and *Low Birthweight*, it accounted for 51% of deaths. This compares with 23% of white and 30% of black singleton deaths related to LBW and its consequences (1983 vital statistics data).[3] The infant mortality rate from these combined causes was 7.9 times higher among twins, compared with singletons.[3]

Congenital Anomalies (ICD-740-759) was the underlying cause for 10% of white and 5% of black twin infant

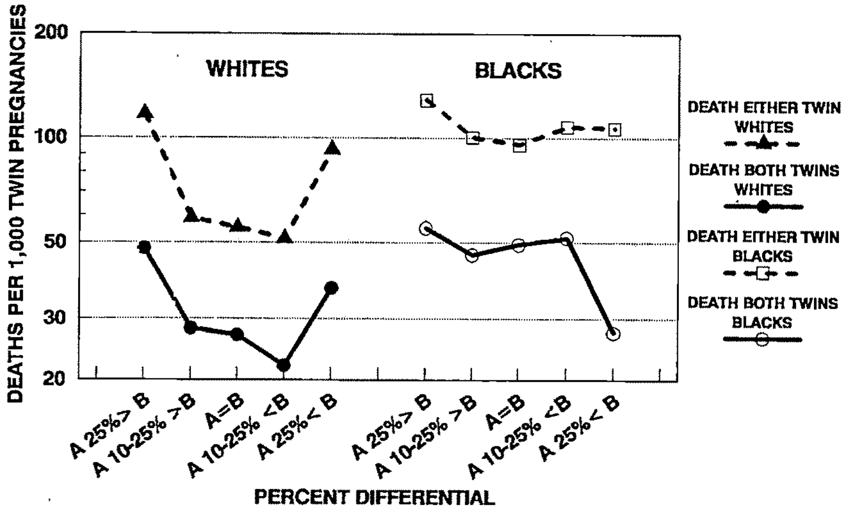

Fig. 2. Twin infant mortality rates by twin pair birth weight differential for black and white twins, from Linked Birth/Infant Death Data Sets: 1983 and 1984 Birth Cohorts for the United States.

deaths. This compares with 27% of white and 14% of black singleton deaths.[3] However, the infant mortality rate from *Congenital Anomalies* was still 1.4 times higher among twins than among singletons.[3] One third of white and 43% of black deaths from *Congenital Anomalies* were due to cardiac conditions. Among whites, deaths caused by *Congenital Anomalies* were 30% to 40% higher among like-gender twin pairs than among unlike-gender pairs.

Table IV presents mortality rates and relative risks for second-born twins compared with firstborn twins for the 10 leading causes of infant death among white twins. Although the overall mortality risk of second-born twins was only 8% greater than that of firstborn twins, mortality risks as a result of respiratory distress syndrome, asphyxia, and congenital anomalies were 19% to 27% higher among second-born twins than among firstborn twins. (Similar patterns were seen for black firstborn and second-born twins, but confidence limits were extremely wide because of the small number of cause-specific events.)

Comment

Despite overall declines in United States infant mortality since the 1950s, twin mortality continues to be four to five times that of singletons. In addition, black twin infant mortality rates are 70% higher than white twin infant mortality rates.

This study contributes to the research on twin infant mortality by using United States linked birth/death vital statistics data to clarify infant and maternal demographic risk factors associated with twin infant mortality. A major strength of the study is the use of 2 years of national data on twin infant mortality, which helps alleviate the sample size and generalizability problems that limit much of the previous research on twins. In addition, this study represents one of the few attempts to match large numbers of twin pair members to look at pair outcomes. On the other hand, a limitation is the lack of detailed data regarding maternal medical risk factors and obstetric management, since the data are limited to information recorded on birth and death certificates.

Maternal risk levels that are based on sociodemographic variables indicate a twofold increased risk for infant mortality among twins born to high-risk black or white women. Although not generally amenable to change, they do help identify particularly high-risk women carrying twin pregnancies, so that interventions to modify behavioral characteristics associated with these risk levels (e.g., smoking or poor nutritional habits) can be implemented.

The analyses of infant risk variables indicate that male, white like-gender twins and twin pairs in which the difference in weight is >25% of the average weight of the pair are at increased risk of infant mortality. Regarding the risk ascribed to birth weight differentials, Erkkola et al.[16] found similar results among a group of 460 Finnish twin pairs. These birth weight differential findings may in part reflect deleterious effects of twin-to-twin transfusion among monochorionic twins sharing vascular anastomoses or other prenatal conditions that impinge differentially on the growth of twin pair members. Ultrasonographic measurements indicating marked size differentials between twin pairs should therefore alert the clinician to higher risk of adverse outcome for either or both members of the pair.

The data regarding gender pair differences in mortality among white like-gender twin pairs support pre-

vious research, which found an increased risk of mortality for like-gender twins, compared with unlike-gender (dizygotic) twins.[5] A partial explanation for this finding is that the like-gender pairs include monozygotic twins, which are known to be at increased risk for placental and cord complications, respiratory distress syndrome, and congenital anomalies.[5] In addition, the larger proportion of white like-gender pairs who are LBW and VLBW, compared with unlike-gender pairs, places them at increased risk for infant mortality. The reason for the lack of protection of unlike gender (dizygosity) with respect to birth weight or survival among black twin pairs is unclear. It may reflect higher maternal complication rates (such as toxemia) among black women, which could negate vascular and nutritional benefits of two independent placental blood supplies on fetal growth. Supporting this hypothesis, Kovacs et al.[17] reported that dizygosity was associated with elevated toxemia rates, compared with monozygosity, and previous research indicates that black women have higher rates of dizygotic twinning, compared with white women. An alternative possibility is that more late fetal deaths (as opposed to early neonatal deaths) are occurring among black like-gender twin pairs, thus lowering black like-gender infant mortality rates. Because we were able to identify only twin pairs where both were live births, we could not investigate this possibility. However, it is interesting that the numbers of male black twin live births are slightly less than the numbers of female black twin live births (opposite to the expected small excess of male births), which would support the possibility of increased fetal deaths among black male twins.

Although our study found only a slight increase in overall mortality for second-born twins, these national data do reinforce previous research suggesting that second twins are at increased risk of death as a result of asphyxia[18] and newborn respiratory disease.[6]

The relative survival advantage of black infant twins in the VLBW category (Fig. 1) parallels patterns noted among black singletons in the LBW range. A potential explanation for this is that black VLBW twins tend to be more stressed in utero because of a variety of maternal sociodemographic and medical risk factors (increased rates of toxemia, poorer nutrition, young age) and that these stressors result in endogenous steroid release with greater physiologic pulmonary maturity of the infant at a given birth weight.[19] On the other hand, Wilcox and Russell[20] have suggested that race-specific birth weight standards should be used when infant mortality in blacks and whites is compared, since the optimal birth weight for survival is markedly lower in blacks. According to their model, if one uses a standardized scale to align the black and white birth weight distributions, then the relative survival advantage of lower birth weight black infants disappears. In any case the survival disadvantage of black twins of normal birth weight is disturbing and suggests that preventable deaths may be occurring.

The extremely high infant mortality seen among both white and black twins probably reflects (1) an accentuation of maternal medical complications in the presence of background sociodemographic risk factors and (2) infant risk factors associated with twinning. Since much of the infant mortality among twins is associated with consequences of very low birth weight, an obvious challenge is to develop strategies that decrease the proportion of twins born at the skewed lower tail of the twin birth weight distribution. Successful interventions to decrease infant mortality among twins should be applicable to other high-risk groups because twins can be viewed as a model demonstrating both demographic and medical risk factors associated with infant mortality. The double jeopardy of both maternal and infant twin risk factors suggests the need for multifaceted approaches to achieve this goal.

Twin delivery: Influence of the presentation and method of delivery on the second twin

Christian Adam, MB,[a] Alexander C. Allen, MD,[b] and Thomas F. Baskett, MB[a]
Halifax, Nova Scotia, Canada

To ascertain the perinatal mortality and morbidity in the second twin as related to its presentation and method of delivery, we reviewed the data on 578 sets of twins delivered from 1980 to 1987 and included 397 sets in whom both twins were ≥1000 gm, without lethal anomalies, and in whom the first twin presented as a vertex. The perinatal outcome comparing twin A (all vertex) with twin B (vertex or nonvertex) with cesarean section or vaginal delivery was analyzed. No statistically significant difference in perinatal mortality or morbidity was found in comparing the nonvertex second twin delivered vaginally or by cesarean section. The one perinatal death and significant perinatal morbidity occurred in infants weighing <1500 gm or at <32 weeks' gestational age. It is concluded that vaginal delivery, irrespective of the position of the second twin, is valid in selected cases as long as fetal weight is >1500 gm and the gestational age is ≥32 weeks. (AM J OBSTET GYNECOL 1991;165:23-7.)

Key words: Twin delivery, perinatal outcome

Controversy continues over the better route of delivery of twins, especially when one or both fetuses are not in cephalic presentation. Cetrulo[1] advocates a liberal cesarean section policy for nonvertex second twins (84% for vertex-nonvertex presentations >34 weeks' gestation) and with this practice has obtained similar mortality and morbidity for each member of the twin pair. Other reports[2-8] document no increase in morbidity and mortality in nonvertex second twins weighing >1500 gm, irrespective of the route of delivery. Doyle et al.[9] assessed twin sets <32 weeks' gestation and reported a 9.6% cesarean section rate for vertex-vertex and vertex-nonvertex presentations combined. They found no difference in mortality or immediate morbidity between vaginal and cesarean delivery.

Slowly rising cesarean section rates from 25% to 40% for twins during the 6-year period 1980 to 1985 in our hospital prompted us to review twin delivery and the associated mortality and morbidity.

Material and methods

From our perinatal data base we reviewed all twin deliveries (578 sets) during the 8-year period 1980 to 1987. The following inclusion criteria were fulfilled by 397 of the original twin sets: (1) twin A in vertex presentation; (2) lethal anomalies excluded; and (3) each twin ≥1000 gm.

All cases with the following mortality and morbidity were categorized with the use of information in the perinatal data base: stillbirths and neonatal deaths ≤28 days; grade III and IV intraventricular hemorrhages (on the basis of ultrasonography); postasphyctic or posttraumatic convulsions; moderate and severe respiratory distress syndrome (on the basis of clinical and radiologic signs); Apgar score <7 at 5 minutes; and trauma (defined as fractures or nerve palsies).

All charts were reviewed to determine the presentation in labor, intrapartum manipulations, mode of delivery, and neonatal outcome. The χ^2 and Fisher's exact test were used to calculate statistical significance when comparing two groups.

Results

Ten stillbirths (all antepartum) were identified in seven twin sets. There was one neonatal death in a second twin delivered vaginally in breech presentation at 31 weeks' gestation. The infant weighed 1880 gm and died of severe hydrops as a result of twin-to-twin transfusion. The perinatal mortality for twins ≥1000 gm and without lethal anomalies was 13.8/1000 or 1.3/1000 for those alive at the onset of labor. This compares with an overall perinatal mortality of 82/1000 for all twins ≥500 gm born from 1980 to 1987.

Once twin sets with antenatal stillbirths (seven) and nonlabor cesarean sections (25) are excluded, the presentation of 365 twin pairs in the early phase of labor and their subsequent presentation and mode of delivery are shown in Table I.

Table II lists the indications for cesarean section in-

IUGR, Intrauterine growth retardation.

volving 79 of the 397 twin sets (20%). In 11 cases, the second twin was delivered by cesarean section after vaginal delivery of the first twin.

Tables III and IV present the perinatal morbidity related to birth weight: 1000 to 1499 gm and ≥1500 gm, respectively. The two main columns identify twin pairs delivered as vertex-vertex or vertex-nonvertex (nonvertex = breech or transverse presentations). These groups are each subdivided into cesarean or vaginal delivery. The numbers include only those infants alive at the start of labor. The only complication not shown in the tables is trauma. There was one case—a fractured humerus in a second twin weighing 3300 gm (600 gm heavier than its companion vertex delivery) and described as a difficult assisted breech delivery.

Table III shows the outcome of infants weighing between 1000 and 1499 gm. Three intraventricular hemorrhages occurred. Both members of one vertex-nonvertex twin pair delivered vaginally had grade III intraventricular hemorrhages. The gestational age was 27 weeks and the deliveries were atraumatic with normal cord pH values. (Twin B was delivered by breech extraction after successful internal podalic version.) Both infants had severe respiratory distress syndrome (RDS). The other intraventricular hemorrhage was associated with difficult breech extraction of the second twin after internal podalic version at 28 weeks' gestation. This infant also had moderate RDS and convulsions. There is no statistical difference in morbidity between vaginal breech delivery and cesarean section in infants 1000 to 1499 gm.

Table IV reviews twins ≥1500 gm. One intraventricular hemorrhage occurred in a second twin and this was associated with an uncomplicated breech extraction at 31 weeks' gestation of an infant weighing 1905 gm. Forceps were applied to the aftercoming head and the cord pH value was normal. The intraventricular hemorrhage in twin A was detected on day 9 when the infant started convulsing and was believed to be related to an anteriovenous malformation and not to birth trauma. The only other case of convulsions was associated with cord prolapse in a first twin subsequently delivered by cesarean section with Apgar scores of 1 and 4 at 1 and 5 minutes, respectively. No statistically significant difference in morbidity was observed between the groups.

Table V analyzes the methods of delivery and manipulation of the second twin in breech and transverse presentations and their relationship to intraventricular hemorrhage. Twenty-nine internal podalic versions were attempted: five failed and twin B was delivered by cesarean section without complications. Twenty-four infants were delivered vaginally after successful internal podalic version and two of these had intraventricular hemorrhage. Both of these infants weighed <1500 gm and were <29 weeks' gestation. Of 41 breech extractions performed, one intraventricular hemorrhage occurred in an infant weighing 1905 gm at 31 weeks' gestation. The extraction was described as uncomplicated and the Apgar scores were 7 and 8 at 1 and 5 minutes, respectively. Of all nonvertex second twins who were delivered vaginally, 13 of the 17 infants (76%)

weighing 1000 to 1499 gm at birth had internal podalic version or breech extraction performed compared with 52 of the 99 infants (52%) with birth weights ≥1500 gm.

As illustrated in Table I, in 218 twin sets delivered vaginally the presentation of both twins was documented in early labor and again after delivery of the first twin. In 121 vertex-vertex combinations, six (4.9%) second twins spontaneously turned to a nonvertex presentation after delivery of the first twin (three had successful external cephalic version, two had internal podalic version and breech extraction, and one had an assisted breech delivery). In addition, one second twin was turned from vertex to breech by internal podalic version and was delivered by breech extraction. In 74 vertex-breech combinations, six (8.1%) second twins spontaneously turned to vertex (two) or transverse (four) presentations. In 23 vertex-transverse combinations, nine (39%) second twins turned to vertex (two) or breech (seven) presentations after delivery of the first twin. There were 15 documented attempts at external cephalic version of the second twin with success in 12 followed by delivery in vertex presentation. Of the three failed external cephalic versions, one was turned to breech and the remaining two had internal podalic version and breech extraction without morbidity.

Table VI illustrates the delivery interval between twins and the mode of delivery and resultant morbidity of the second twin; 90% of vertex and 97% of nonvertex second twins were delivered within 30 minutes of the first twin. The longest delivery interval for a vertex twin was 277 minutes compared with 64 minutes for a nonvertex twin. There was no significant difference in low Apgar scores between delivery intervals <15 minutes and those between 15 and 30 minutes. All three intraventricular hemorrhages occurred in twins delivered within 15 minutes of their companion twin. Prolongation of the delivery interval >30 minutes did not add to morbidity, but overall numbers are low in this group. Cesarean section was performed for three vertex twins after intervals >1 hour (69, 78, and 277 minutes).

Comment

One of the main areas of controversy in twin pregnancies is the delivery of vertex-nonvertex presentations. We are aware of only one small prospective randomized study[3] that is available and therefore one has to rely on local experience and nonrandomized studies to formulate a policy for delivery.

In our review of vertex-vertex and vertex-nonvertex twin sets without lethal anomalies and with both twins ≥1000 gm, we recorded an 80% vaginal delivery rate. Perinatal mortality was not influenced by vaginal breech delivery of the second twin. However, we realize

Table V. Twin B nonvertex: Relationship of method of delivery to intraventricular hemorrhage

	1000-1499 gm		*≥1500 gm*		*Total*	
	IVH	*No. of infants*	*IVH*	*No. of infants*	*IVH*	*No. of infants*

External cephalic version	6	2	4
Internal podalic version	21	2	1
5 min Apgar score <7	14	2	0
Intraventricular hemorrhage	3	0	0

that because of our low numbers and the paucity of adverse effects the possibility of a β-error could exist. In reviewing morbidity rates, the presence of three significant intraventricular hemorrhages in nonvertex second twins delivered vaginally raised concern. Internal podalic version and breech extraction were performed in the two second twins weighing <1500 gm with intraventricular hemorrhage. In one twin set in whom both members had grade III intraventricular hemorrhage and severe RDS, it is difficult to implicate the version and delivery as the probable cause of hemorrhage. However, the other case was characterized as being a difficult delivery of both first and second twins, resulting in low Apgar scores in each and an intraventricular hemorrhage in twin B. In twins weighing >1500 gm, one intraventricular hemorrhage was associated with an uncomplicated breech extraction with forceps applied to the aftercoming head. This infant also had moderate RDS that may have been a contributing factor.

Three fourths of the internal podalic versions were performed in twins weighing >1500 gm and no significant neonatal morbidity was found in this group. In analyzing these results, we believe that this procedure is safe in twins weighing >1500 gm. This is in agreement with reports from Rabinovici[10] and Chervenak.[2,6] We realize that this subgroup of patients may have been delivered by operators comfortable with and experienced in internal podalic versions, hence giving acceptable results that may not be reproducible with less experienced physicians. However, early recourse to cesarean section was undertaken in those cases of attempted version that proved difficult. By so doing, there were no cases of major morbidity in our cesarean sections performed for the second twin alone. In spite of our low numbers this indicates that this procedure seems to be a safe alternative to vaginal delivery and should be considered if difficulty is encountered in delivery of the second twin.

Breech extraction alone was performed in 41 second-twin deliveries with one case of intraventricular hemorrhage. When combined with internal podalic version and breech extraction, a total of 65 deliveries are documented. Fifty-two of these (80%) occurred in twins weighing >1500 gm, and only one intraventricular hemorrhage was encountered. Unfortunately, it is difficult to compare this group with second twins delivered by spontaneous breech delivery or cesarean section because of low numbers and the rarity of poor outcome. In this retrospective review we do not know why some breech presentations were delivered by assisted breech delivery and others by breech extraction. Indications for prompt delivery (e.g., fetal distress) along with operator bias and experience were probably the main reasons. We do not advocate routine breech extraction but rather our results support the work of others that show selected breech extraction to be an acceptable method of delivery in twins >1500 gm.[2,3,5-8]

Twelve of 15 documented external cephalic versions performed in this group were successful. Of the three failures, all had uneventful vaginal breech deliveries. Although our numbers are very small, this compares favorably with Chervenak's[11] report of a 72% success rate, whereas not showing the complications encountered by Gocke et al.[12] in their study of 41 versions. Further studies are needed to show whether this procedure is as safe as originally thought and its role as an alternative to cesarean section of the nonvertex second twin <1500 gm should be further explored.

Our experience is in agreement with that of Rayburn et al.[8] in that as long as fetal surveillance is maintained, there need be no rigid time restriction for delivery interval between twins. We advocate conservative management and oxytocin augmentation for delay with both vertex and frank or complete breech presentations. Should the second twin present as a footling breech then breech extraction can be considered. If a transverse lie is encountered we favor external cephalic version. Should this fail, internal podalic version and breech extraction should be carried out. If the operator is uncomfortable with this procedure early recourse to cesarean section is an alternative.

We conclude therefore that it is reasonable to allow labor and vaginal delivery, irrespective of the presentation of the second twin, as long as fetal weight is ≥1500 gm and the gestational age ≥32 weeks. This accounts for >85% of vertex-nonvertex twin pairs (≥500 gm) entering labor in our series. In smaller twins, a dilemma is posed: the numbers are low, especially involving twins delivered by cesarean section, and yet there were two cases of major morbidity associated with vaginal delivery that involved internal podalic version and breech extraction in second twins weighing between 1000 and 1499 gm. Although no statistical differences were seen, we believe that internal podalic version and breech extraction should be avoided if possible in this group, and that external version or cesarean section may be associated with less major morbidity.

Cigarette smoking during pregnancy in relation to placenta previa

Michelle A. Williams, SM,[a] Robert Mittendorf, MD, MPH,[a, c]

Stephen C. Schoenbaum, MD, MPH,[f] and David R. Genest, MD[e]
Boston, Massachusetts

To evaluate the relationship between cigarette smoking and the occurrence of placenta previa, we used interview and medical record data to conduct a case-control analysis of 69 placenta previa cases and 12,351 controls. The unadjusted relative risk estimate of placenta previa for women reported to have "ever smoked" during pregnancy relative to nonsmoking mothers was 1.9 (95% confidence interval, 1.2 to 3.0). The risk rose after adjusting for potential confounders (odds ratio, 2.6; 95% confidence interval, 1.3 to 5.5). In contrast to a previous report, the duration of smoking was not an independent risk factor for placenta previa. These results suggest that cigarette smoking during pregnancy is a determinant of placenta previa. Carbon monoxide hypoxemia, which is one possible mechanism for this association, may result in compensatory placental hypertrophy. Placentas with increased surface areas are more likely to cover the cervical os, causing placenta previa. (AM J OBSTET GYNECOL 1991;165:28-32.)

Key words: Placenta previa, pregnancy, smoking, risk factor

Although placenta previa is uncommon, it is a significant cause of maternal and perinatal morbidity and mortality. Placenta previa has been reported to occur in 3.3 to 9.9 per 1000 deliveries.[1, 2] However, its cause is poorly understood. Risk of placenta previa has been found to increase with increasing parity, maternal age, previous induced and spontaneous abortions, previous cesarean section, a history of dilatation and curettage, and short maternal stature; it also occurs more frequently with singleton male pregnancies and twin pregnancies of both sexes and when gestation takes place at high altitude.[1-10]

Two prior studies found a positive association between placenta previa and maternal cigarette smoking during pregnancy.[5, 11] Meyer et al.[5] observed a 25% and 92% increase in the prevalence of placenta previa for smokers of less than one pack and smokers of one or more packs of cigarettes per day, respectively. More recently, Kramer et al.[11] also found an association between smoking and placenta previa (odds ratio, 1.9; 95% confidence interval, 1.5 to 2.8).

Naeye[12] reported that the duration of maternal cigarette smoking was associated with placenta previa. He found that the frequency of placenta previa was more strongly associated with the number of years mothers had smoked than with their smoking habits during pregnancy. In this study we evaluated the association between cigarette smoking and placenta previa in a large cross-sectional data base.

Material and methods

The Delivery Interview Program, conducted at the Boston Hospital for Women from August 1977 to March 1980, was designed to study the occurrence of adverse outcomes of pregnancy.[13] Information was obtained by personal interviews and medical records review. During the study period 14,458 mothers (84.4% of all deliveries) were asked to participate in the study. Some mothers were not asked to participate because there were too few interviewers (14.1%) or because their physicians would not grant permission for participation in the study (1.4%). When too few interviewers were available, patients were selected randomly. Of the mothers with singleton deliveries, 90.0% of those approached (12,825 women) were interviewed. The reasons for not having been interviewed were early discharge (5.5%), refusal to be interviewed (3.0%), the presence of a language barrier (1.6%), and medical conditions precluding an interview (0.1%). The interview provided information on demographic character-

istics, previous contraceptive practice, medical and reproductive histories, cigarette smoking habits, and exposure to other possible risk factors. Information regarding the duration of smoking; smoking status at the time of conception; and the average number of cigarettes smoked per day during the first, second, and third trimesters, respectively, was obtained from mothers who had ever smoked. Information was collected from the medical records regardless of whether an interview had occurred. Information regarding pregnancy outcome and condition of the newborn was abstracted from the mothers' and infants' medical charts. Completed interviews and medical records information were available for 12,718 women who were delivered of singleton infants.

For this analysis, cases consisted of nondiabetic women with singleton deliveries whose medical records indicated a physician's diagnosis of placenta previa ($n = 69$). Detailed information regarding gestational age at diagnosis and type of placenta previa (marginal, partial, or total) were not available. The controls were the 12,351 nondiabetic women with singleton deliveries that were not complicated by placenta previa. This study was restricted to nondiabetic women because only 2.3% of the study population were diabetic. Women with a diagnosis of abruptio placentae (independent of placenta previa) indicated on their medical records ($n = 135$) were excluded from this analysis. Abruptio placentae, another cause of third-trimester bleeding, has been shown to be associated with maternal cigarette smoking during pregnancy.[5] Analyses including these women yielded results similar to those reported here.

Women were considered to be cigarette smokers during pregnancy if they had reported ever having smoked during the first or second trimester. Three levels of cigarette smoking during pregnancy were considered: nonsmokers, smokers of 1 to 9 cigarettes per day, and smokers of ≥10 cigarettes per day. Three levels of the duration of cigarette smoking were also considered: never smokers, smokers for 1 to 5 years, and smokers for ≥6 years.

To estimate the risk of placenta previa associated with cigarette smoking, odds ratios were calculated. Unconditional logistic regression was used to adjust for potential confounding variables (included as either categorical or continuous variables) and to derive maximum likelihood estimates of combined relative risks and 95% confidence intervals.[14] Adjusted dose-response relationships between cigarette smoking and placenta previa were evaluated in multiple logistic regression models, with cigarette smoking treated either as a continuous variable or as a series of dichotomous variables. Level of statistical significance was fixed at $p = 0.05$. We assessed confounding by entering potential confounders into a logistic regression model one at a time and by comparing the adjusted and unadjusted odds ratios.[14] The final logistic regression model included variables that had altered the unad-

justed odds ratio by at least 10%. Variables with a priori interest also were added to the final model.

Results

The prevalence of placenta previa at the Boston Hospital for Women from 1977 to 1980 was 5.5 per 1000 deliveries among nondiabetic women. Selected delivery and infant outcomes are presented in Table I. Cases were approximately four times more likely to have been delivered by cesarean section than were controls. The mean length of gestation was 36.1 weeks for cases and 39.7 weeks for controls. Some sociodemographic, medical, and behavioral characteristics of cases and controls are presented in Table II. The mean age of cases was 29.9 years as compared with 27.7 years for controls. Cases were of higher parity than were controls. Twenty-seven cases (39.1%) and 2098 controls (17.0%) had a history of one or more spontaneous abortions. Cases were twice as likely to have had a previous cesarean section than were controls. Cases also reported a history of in utero exposure to diethylstilbestrol (DES) more frequently than did controls. Advanced maternal age, higher parity, previous in utero exposure to DES, previous cesarean section, previous spontaneous abortion, and consumption of an average of three or more cups of coffee per day during pregnancy were all statistically significant risk factors for placenta previa in this population.

A higher proportion of cases (44.9%) than controls (30.3%) reported smoking during pregnancy. Smokers for a duration of ≥6 years were more likely to have continued smoking during pregnancy (68.4%) than were smokers of 1 to 5 years (31.6%) (not shown in tables). Women who smoked during the first two trimesters of pregnancy had a 90% increase in risk for placenta previa (odds ratio, 1.9; 95% confidence interval, 1.2 to 3.0) compared with women who did not smoke during pregnancy. Controlling for potential confounders (race, maternal age, payment status, marital status, parity, previous spontaneous abortions, previous cesarean section, previous in utero exposure to DES, coffee consumption during pregnancy, and the duration of cigarette smoking) resulted in a relative risk estimate of 2.6 (95% confidence interval, 1.3, 5.5 Table III). Among smokers a dose-response gradient between placenta previa and the number of cigarettes smoked per day during pregnancy was not present when the number of cigarettes smoked during pregnancy was represented as a continuous variable (p value for linear trend, 0.75).

Compared with never-smokers, women who smoked throughout pregnancy had a threefold increase in risk for placenta previa (adjusted odds ratio, 3.1; 95% confidence interval, 1.2 to 8.1). For women who stopped smoking before conception (as compared with never smokers), the adjusted odds ratio was 1.3 (95% confidence interval, 0.5 to 3.3). For women who stopped smoking during the first trimester (as compared with never smokers), the adjusted risk was 1.9 (95% confidence interval, 0.6 to 6.7). Among former smokers estimates of the relative risk for placenta previa did not vary as a function of the duration of cigarette smoking (data not shown). The small number of women in these categories, however, necessitates caution in interpretation.

Crude and adjusted estimates of relative risk for women in each of the duration of cigarette smoking categories as compared with never smokers are shown in Table IV. The duration of cigarette smoking was not found to be an independent risk factor for placenta previa when smoking during pregnancy was considered. Women who reported smoking for 1 to 5 years

Table IV. Frequency of cases and controls, crude and adjusted odds ratios, and 95% confidence intervals for duration of smoking and placenta previa*

Duration of cigarette smoking	*Placenta previa cases (N = 69) (No.)*	*Control subjects (N = 12,351) (No.)*	*Crude odds ratio*	*Adjusted odds ratio*	*Adjusted 95% confidence interval*
Never smoker	25	5704	1.0	1.0	–
Smoker of 1-5 yr	11	2726	0.9	0.9	0.4-2.0
Smoker of ≥ 6 yr	33	3921	1.9	1.0	0.5-2.2

*Adjusted for maternal cigarette smoking status during pregnancy, race, maternal age, payment status, marital status, parity, previous spontaneous abortions, previous cesarean section, previous in utero exposure to DES, and coffee consumption.

did not have an increase in risk for placenta previa (adjusted odds ratio, 0.9; 95% confidence interval, 0.4 to 2.0). Similarly, women who had smoked for ≥6 years were not at increased risk for placenta previa as compared with never smokers (adjusted odds ratio, 1.0; 95% confidence interval, 0.5 to 2.2). A continuous variable representing the duration of cigarette smoking in years was not statistically significant in a logistic regression model confined to ever smokers ($p = 0.39$ for linear trend).

Adjusted odds ratios for maternal cigarette smoking during pregnancy and other variables entered into the final logistic regression model are presented in Table V. In addition to maternal cigarette smoking during pregnancy, prior spontaneous abortions, prior cesarean section, prior exposure to DES in utero, and increasing parity were independent and statistically significant risk factors for placenta previa.

Comment

Using cross-sectional data collected from a largely white obstetric population, we found the crude relative risk of placenta previa to be 1.9 (95% confidence interval, 1.2 to 3.0) among women reported to have ever smoked during pregnancy. Adjusting for potential confounders enhanced the observed positive association between cigarette smoking and placenta previa (adjusted odds ratio, 2.6; 95% confidence interval, 1.3 to 5.5). A dose response between the number of cigarettes smoked per day during pregnancy and the risk for placenta previa was not demonstrated.

The statistically significant increased risk of placenta previa associated with increasing parity and previous spontaneous abortion demonstrated in this report is consistent with other studies.[2, 3, 5, 6, 15] Results from two previous investigations support the hypothesis that cigarette smoking during pregnancy is an independent risk factor for placenta previa.[5, 11] Kramer et al.[11] noted a 90% increase in risk of placenta previa among women who smoked as compared with nonsmokers (adjusted odds ratio, 1.9; 95% confidence interval, 1.5 to 2.8).

The duration of cigarette smoking was not found to be an independent risk factor for placenta previa. This finding differs from that reported by Naeye.[12] In our study smoking for a duration of ≥6 years was associated with placenta previa in the initial univariate analyses. However, when cigarette smoking during pregnancy and confounders were added to a logistic regression model, the association between the duration of cigarette smoking and placenta previa was not statistically significant.

It is unlikely that bias is responsible for the associations observed in this study. There is no indication that the observed association between placenta previa and cigarette smoking was due to information bias because the trained interviewers were kept unaware of the study objective. A systematic selection bias seems unlikely because women were included in the analysis without reference to their exposure or outcome status. Some recall bias on the part of the placenta previa cases is possible and could have resulted in an overestimation of the strength of the positive association observed in this study. Nondifferential misclassification of the number of cigarettes smoked during pregnancy would tend to result in an underestimation of the strength of this association[16] between cigarette smoking and placenta previa.

Table V. Adjusted* odds ratios of placenta previa and 95% confidence intervals according to selected characteristics

Characteristic	*Adjusted odds ratio*	*Adjusted 95% confidence interval*
DES in utero	4.4	1.6-12.4
Current cigarette smoker	2.6	1.3-5.5
Prior cesarean section	1.8	1.0-3.5
Prior spontaneous abortions (No.)	1.4	1.1-1.8
Coffee ≥ 3 cups/day	1.3	0.7-2.5
Parity (No.)	1.3	1.1-1.6
Duration of cigarette smoking (yr)	1.0	0.9-1.0
Maternal age (yr)	1.0	1.0-1.1
Medicaid recipient	0.9	0.4-2.3
Single	0.7	0.2-1.9
Black	0.5	0.2-1.3

*Adjusted with the use of a multiple logistic regression model.

The observed association between cigarette smoking and placenta previa has compelling biologic plausibility. Hypoxemia as a result of exposure to nicotine and carbon monoxide from maternal cigarette smoking during pregnancy may result in compensatory placental hypertrophy, thus increasing the likelihood of encroachment of the placenta on the cervical os. Investigators have demonstrated an acute decrease in uterine blood flow immediately after maternal infusion of nicotine,[17-19] and nicotine, which is a very potent vasoconstrictor, has been shown to concentrate in the placental tissue of vertebrates.[20, 21]

Three studies that compared the placentas of smokers and nonsmokers demonstrated a 0.69% to 3.63% increase in placental weight among smokers as compared with nonsmokers.[22-24] One of these studies noted that increased placental weight was accompanied by a 1.85% to 2.37% decrease in placental thickness and by a 0.35% to 1.30% increase in the smallest placental diameter in the placentas of smokers as compared with those of nonsmokers.[24] The study findings suggest that, in comparison with nonsmokers, women who smoke during pregnancy have heavier, thinner placentas with larger surface areas; these features could result in an increased likelihood of placental encroachment on the cervical os.

Investigators have found both light microscopic and electron microscopic abnormalities in the placentas of smokers, such as fibrinoid changes in the maternal decidual arteries, fibrotic peripheral villi, villous hyperplasia, marginal placental necrosis, and hypotrophic and avascular stem villi, which they have considered to be evidence of chronic hypoxemia and ischemia.[17, 20, 25] In addition, the number of placental infarcts was found to be increased in smokers.[12] Notably, similar morphologic changes have been observed in placentas from gestations that occurred in the relatively hypoxic environment of high altitude.[9] Furthermore, McClung[9] has reported a higher prevalence of placenta previa at high altitude than at sea level.

Both laboratory and epidemiologic studies provide evidence of an association between placenta previa and cigarette smoking that is biologically plausible. The striking similarity of morphologic changes in placentas observed at high altitude and in the placentas of smokers supports the hypothesis that hypoxemia may be an important determinant in the occurrence of placenta previa.

count six

The innovative efforts made by Organon in gynaecology are making such headway that its broad product portfolio now approaches completeness:

1 oral contraceptives

2 hormone replacement therapy

3 gynaecological disorders

4 obstetrics

5 fertility stimulation

6 diagnostics

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

the human signature

The extensive portfolio of gynaecological products now available from Organon is the result of a tradition of innovation plus an appreciation of the needs of both women and the medical profession.

Generations of women have benefited from the fruits of this research – from oral contraceptives, to hormone replacement therapy and gonadotrophins. Organon's fertility stimulating products have for generations been relied upon throughout the world. Living proof of Organon's commitment to worldwide gynaecological service.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: **Robert L. Barbieri, MD**
State University of New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research and serving as a long-term, practical resource.

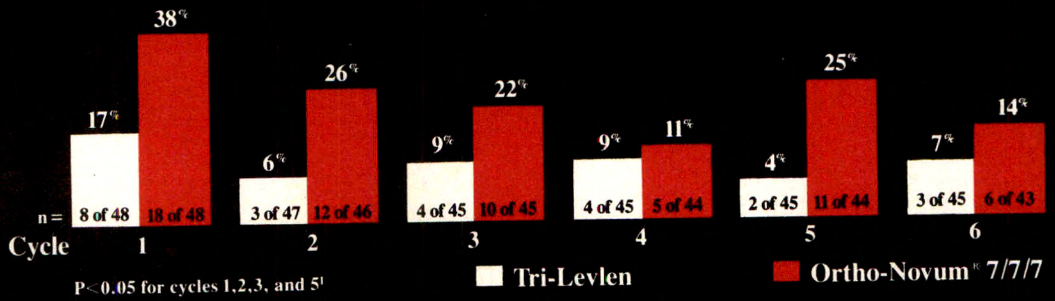
A red spot means a lot to a woman.

A red spot may mean breakthrough bleeding

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]



P< 0.05 for cycles 1,2,3, and 5[1]

n = number of women with a bleeding event occurring during a cycle.

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

Ortho-Novum® is a registered trademark of Ortho Pharmaceutical Corp.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction*. An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism*. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women witb predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases*. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives*. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease*. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use*. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's–but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs*. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia*. Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions*. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy*. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease*. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects*. Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure*. An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache*. The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities*. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

Medication in early pregnancy: Prevalence of use and relationship to maternal characteristics

Simone Buitendijk, MD, MPH,[a] **and Michael B. Bracken, PhD, MPH**[a, b]
New Haven, Connecticut

Medication use was assessed in a population of 4186 women who were delivered of infants at Yale–New Haven Hospital, New Haven, Connecticut, between 1980 and 1982. The frequency of over-the-counter and prescription drug use, and the association of such use with maternal characteristics was studied. Of all women, 66% used at least one drug. The mean number of drugs used by all subjects was 1.3 and, among drug users, 2.9. Of all drugs used, 68% were over-the-counter and 32% were prescription preparations. Internal analgesics, autonomic drugs, antiinfective agents, and antacids were most frequently used. Women who used prescription drugs were also more likely to use over-the-counter medications. Maternal characteristics that were associated with an increase in both over-the-counter and prescription drug use were being white, smoking more than 20 cigarettes a day, using alcohol, using caffeine, and smoking marijuana. These findings suggest that women who engage in "risk-taking behavior" during pregnancy are also more likely to use medications while pregnant. (AM J OBSTET GYNECOL 1991;165:33-40.)

Key words: Drugs, medications, risk-taking behavior, pregnancy

During the past 25 years there has been increasing awareness of the potentially harmful effects of drugs and chemicals on the developing fetus. However, the mechanism of most teratogenic compounds is still poorly understood and very little information exists concerning the absolute safety of the use of specific medications during pregnancy.

Knowledge of the potential danger of medication use during pregnancy and recognition of the fact that important information is still lacking should warrant conservative use of medications. Unfortunately, medication use during pregnancy is quite prevalent and does not appear to be decreasing. During the past 25 years, several studies of the prevalence of drug use during pregnancy have been carried out.[1-6] Although the studies differ in several aspects (patient population, year of study, type of drugs studied, size of study), they all report a large number of drugs being used by pregnant women: 44% to 92% of women using at least one medication, with an average of 3 to 5.5 medications per woman among users. There also does not appear to be a downward trend in frequency of use in more recent studies.

Table I. Prevalence of prescription and nonprescription drug use in pregnancy among women delivered of infants at Yale–New Haven Hospital, 1980 to 1982

No. of drugs	*Frequency*	%
0	1425	34.1
1	1351	32.3
2	793	18.9
3	348	8.3
4	156	3.7
5	58	1.4
6	28	0.7
7	15	0.4
8	6	0.1
9	3	0.1
10	1	—
12	1	—

Total number of drugs used: 5265. Mean number of drugs used by all subjects: 1.3. Mean number of drugs used by women taking at least one medication: 2.9.

No previous research, to our knowledge, has assessed the relationship of medication use with maternal characteristics other than age and race, or to exposures other than smoking. We are also unaware of prior research into either the relationship of maternal characteristics and drug use for over-the-counter and prescription drugs separately, or studies looking at the relationship between over-the-counter and prescription drug use. This study addresses these questions in a relatively large population of pregnant women.

Material and methods

tenance organization, or a hospital clinic, and who were scheduled for delivery at Yale–New Haven Hospital, New Haven, Connecticut, were invited to participate in the study. Subjects were recruited between May 12, 1980, and March 12, 1982. Of 6219 women identified at the start of the study, 4926 were willing to be contacted and met the eligibility criteria. Valid interviews were completed for 4186 (85%) of the eligible subjects. The interview was conducted by trained interviewers and contained questions concerning pregnancy history, demographic characteristics, and exposure to other possible risk factors. Most interviews took place in the woman's home, the majority a few weeks after the first prenatal visit. Of all subjects, 80% were interviewed before week 22 of the pregnancy. A more detailed description of subject selection and data collecting procedures has been provided elsewhere.[7]

To ascertain their exposure during the critical period of organogenesis, women were asked whether they had taken any medication in each of the 12 weeks since their pregnancy started (i.e., since the estimated day of conception) for any specific indication. A list of 23 different indications such as fluid retention, nausea, constipation, and epilepsy was read to the respondent. For every affirmative answer the name of the specific drug or medication was asked. Where possible, women were asked to show the interviewer the package with the name of the medication. Over-the-counter drugs were coded in accordance with the listing from the *Handbook of Nonprescription Drugs*.[8] The prescription drug listing was coded according to the American Hospital Formulary Service.[9] Vitamins, iron supplements, and food supplements were excluded from the drug listings.

Respondents were asked whether and how often since their pregnancy started they had consumed different types of alcohol and how many drinks, on average, they had at one time. They were asked whether and how often they had used marijuana or hashish since their pregnancy started. Information on smoking was obtained by asking whether a woman had smoked during each of the months of the pregnancy and, if she had, how many cigarettes, on average, per day.

First we displayed the frequency of overall and individual use. Next, a χ^2 analysis was carried out to assess the relationship between frequency of over-the-counter and prescription drug use. Further, to study whether maternal characteristics influence the extent of drug use, analyses were carried out to assess frequency of medication use by a number of maternal variables, both for all drugs and for prescription and over-the-counter drugs separately. Finally, we carried out logistic regression analyses with the use of the Statistical Analysis System (SAS)[10] to assess the independent relationship of maternal characteristics to prescription, over-the-counter, and total use of drugs.

Results

Of the 4186 study subjects, 67.0% were younger than 30 years of age, 78.1% were white, 78.2% were married, 58.7% had more than 12 years of education, and 46.0% were nulliparous. During the first trimester of pregnancy, 34.1% of women abstained from medication use, 32.3% used one drug, 27.3% used two or three, and

6.4% used four or more drugs. A total of 5265 drug uses was recorded, an average of 1.3 per woman. Among all women using at least one medication, 2.9 drugs were used on average (Table I). Of the total of 5265 reported drug uses, 5180 (98.4%) were coded by the interviewer and could subsequently be classified as a prescription or over-the-counter drug. Table II shows the frequency of drug use in the two categories. Of all women, 27.3% used prescription drugs, 19.2% used one, 7.2% two or three, and 0.9% four or more. A total of 1638 prescription drugs were used, an average of 0.4 per woman for the entire cohort. Of all women, 54.9% used over-the-counter drugs, 34.6% used one, 18.4% two or three, and 2.1% four or more. A total of 3542 over-the-counter drugs were used, an average of 0.9 per woman for the entire cohort.

We cross-classified use of over-the-counter and prescription drugs (Table III). The association between frequency of prescription and over-the-counter drugs was highly significant ($p < 0.0001$), indicating that women who use prescription medication are also more likely to use over-the-counter medications and vice versa.

Over-the-counter drugs were grouped into their indication categories and the frequency of use in each was calculated (Table IV). Internal analgesics are the most frequently used and are used by more than half of all the women in this cohort. They also account for more than 40% of all drugs used in this study. Table V shows the frequency of prescription drug use. Autonomic drugs were most frequently used. Of all women in the cohort, 10% used autonomic drugs and they constituted 27.5% of all prescription drug use.

Table VI shows the most frequently used over-the-counter and prescription drugs. Among the over-the-counter preparations, Tylenol analgesic is used most, accounting for more than 40% of all nonprescription drugs, and used by 36.5% of all women in the cohort. The most frequently used prescription drugs are the parasympatholytic agents (25% of all prescription drugs), of which Bendectin antihistamine was the single most prescribed drug, used by 9.2% of all women in the cohort.

Table VII shows the distribution of maternal characteristics by drug exposure. Of all women 31.9% smoked at least one cigarette a day at the time of interview, 69.3% drank some alcohol, 76.8% had exposure to caffeine, and 9.7% used marijuana. Women who used drugs were significantly more likely to be older, married, white, and college-educated. They were also more likely to have consumed alcohol, caffeine, and marijuana. No relationship was found between frequency of drug use and cigarette smoking or employment status.

A similar analysis for over-the-counter drugs was performed. We found similar associations with older age, being married, being white, being college-educated, use of caffeine, alcohol, and marijuana, and more frequent use of over-the-counter drugs. Prescription drugs were also similarly analyzed. Again the association with age, marital status, ethnicity, education, caffeine use, and marijuana use were significant. No relationship was found between alcohol use and pre-

scription drug use. No relationship was found between cigarette smoking and over-the-counter or prescription drugs. Employment status was only significant for over-the-counter drug use, with employed women being more likely to be frequent drug users.

Logistic regression analysis was used to estimate the independent effects of age, education, ethnicity, employment, marital status, marijuana use, smoking and alcohol use on total medication use. The variables that were retained in the model are shown in Table VIII. White women, women smoking more than 20 cigarettes per day, and those using alcohol or caffeine are significantly more likely to use medications.

Comment

This study indicates that two thirds of pregnant women take some medication during the first trimester of pregnancy, the period during which the fetus is most

susceptible to teratogenic effects. The number of women using medications is similar to that found in prior studies[1-6] although the average number of drugs consumed seems to be slightly lower in our study. Earlier studies found that 43.6% to 92.0% of all women used at least one drug, with an average of 3.0 to 5.5 drugs being used throughout the pregnancy among women using drugs. Our findings were that 55.9% of all women used at least one drug. An average of 1.25 drugs were used during the first trimester by all women and an average of 1.9 by those using at least one medication. It is possible that we found a lower average because, unlike some other studies, we only monitored use during the first trimester or because of other differences in the study population.

The drugs most frequently reported in our study were internal analgesic products, parasympatholytic agents, penicillin, antitussives, and cold and allergy preparations. The same findings were reported in earlier studies.

Use of prescription and over-the-counter drugs was significantly related: women who used drugs from one group were also more likely to use drugs from the other. This is an interesting finding given that differences exist in the way each type of medication is obtained. It is possible that women who suffer from certain conditions that require prescription medication are also more likely to buy over-the-counter drugs for the same condition. It is also possible that a certain "medication-taking behavior" exists: women who use over-the-counter drugs might also be more likely to obtain prescription drugs. Yet another explanation might be economic: women who cannot afford medications are likely to not use either over-the-counter or prescription drugs.

Our analyses show that there do not seem to be major differences in the maternal characteristics of women who frequently use over-the-counter versus prescription drugs during pregnancy. In this analysis, the maternal characteristics associated with low frequency of drug use were being nonwhite, unmarried, and less educated. Being unemployed was significantly related to greater over-the-counter drug use but not with prescription drug use. Unemployed women may be less able to afford regular physician office visits and, consequently, be less likely to receive a prescription. Of the risk-taking behaviors known to be associated with adverse pregnancy outcome (especially low birth weight),

marijuana use was significantly related to greater frequency of drug use in all analyses. Increased alcohol drinking was associated with over-the-counter and overall drug use but not with prescription drug use. Cigarette smoking was related to prescription drug use as well as overall drug use. It was not related to over-the-counter drug use. White women were more likely to use both types of medications. White women may be better able to afford medications than nonwhite women, but a related explanation could be that they are more likely to receive prenatal care and to subsequently have medications prescribed to them. If this explanation indeed holds true, improvement in prenatal care may diminish the difference in frequency of drug use between white and nonwhite women. However, when a separate analysis was carried out on race and frequency of use of Bendectin antihistamine, women in all racial groups used Bendectin antihistamine with the same frequency. Bendectin antihistamine was the most frequently used prescription drug, prescribed for nausea in pregnancy. If receiving prenatal care is indeed related to frequency of prescription drug use, use of Bendectin antihistamine would have been expected to be higher among white women.

The analysis shows that women who are white, use marijuana, are heavy smokers, drink alcohol, and use caffeine were more likely to use medications. These are independent risk factors and the observed link between more frequent medication use and other risk-taking behaviors occurs in white and nonwhite women. It is possible that a woman's use of cigarettes, marijuana, caffeine, or alcohol might directly influence her medication-taking behaviors. Women might become more aware of the possible dangers of medication use during pregnancy, just as they are of the hazards of smoking or drinking. Women who try to avoid any dangerous exposures when pregnant might also avoid medication use. Alternatively, physicians may be more likely to prescribe to certain women because of their social characteristics or medical condition. Cigarette smoking, for instance, has been related to a greater risk of upper respiratory problems. These conditions may require increased medication use.

Table VIII. Final model for logistic regression analysis on total drug use, Yale–New Haven Hospital, 1980 to 1982

Maternal characteristic	*Odds ratio*	*95% Confidence interval**
White race	0.58	0.46-0.71
Smokes 1-10 cigs/day	1.03	0.83-1.28

Cigs, Cigarettes. Reference categories are being nonwhite, nonsmoking, and not using alcohol or caffeine.

Calculated by: $e^{(\beta \pm 1.96 \times SE\ \beta)}$

Because so little is known about the teratogenic potential of most drugs (prescription as well as over-the-counter drugs) only those drugs should be used for which a large body of information is available, and then only when necessary. Clearly, some drugs, such as antiepileptic agents, may need to be taken even without full knowledge of their teratogenic potential. However, this study indicates that the great majority of drug use in pregnancy is not for serious conditions. Bendectin antihistamine was the single most widely used prescription drug in the study. As a result of numerous studies,[11] Bendectin antihistamine is now generally recognized not to be teratogenic. However, it is ironic (given that Bendectin antihistamine has been withdrawn from the market) and sobering to realize that Bendectin antihistamine was in widespread use long before evidence of its safety was well documented. Physicians should be careful when prescribing to pregnant women and should always inquire about the possibility of pregnancy before prescribing to any woman of childbearing age. Pregnant women should learn to be more critical toward the use of drugs and should first try alternative treatments for common pregnancy discomforts. For example, Bendectin antihistamine was used by 30% of women in some reports, which would appear to be well above the proportion of women who suffer serious nausea and vomiting in early pregnancy.[11] This overuse implies underuse of nonpharmacologic treatment in mild cases.

Aspirin was the second most frequently used over-the-counter drug in this cohort. Aspirin affects prostaglandin synthesis and given before delivery, it can, even in low doses, affect the clotting ability in the newborn.[13] The relationship between aspirin and congenital birth defects remains controversial, in spite of the fact that several studies have been undertaken.[2, 14, 15]

Acetaminophen was the most widely used of all drugs in this study. There is no evidence of possible teratogenic properties[2] and, unlike aspirin, acetaminophen does not increase the risk of fetal hemorrhage when given to the mother at term.[16] All this considered, acetaminophen is recommended when an analgesic or antipyretic is needed in pregnancy. This means that in the case of aspirin use in this cohort we know that an equally effective, but possibly less harmful alternative, would have been available. In view of our still inadequate knowledge about the safety of most drugs, pregnant women should be counseled about the potential hazards of medication use during pregnancy. Ideally, a woman should stop taking drugs as much as possible as soon as she plans to become pregnant or when she suspects she might be pregnant.

Extensive pulmonary embolism presenting as severe adult respiratory distress syndrome after surgical resection of a cornual pregnancy

Derek J. tenHoopen, MD, David M. Sherer, MD, Jacques S. Abramowicz, MD, and Peter J. Papadakos, MD
Rochester, New York

A rare case of severe adult respiratory distress syndrome associated with a Po_2 of 9 mm Hg after surgical resection of a cornual pregnancy at 10 weeks' gestation was treated successfully with positive end-expiratory pressure. The underlying cause, extensive pulmonary embolism, was subsequently revealed. The patient survived without residual brain damage. The possible causes of adult respiratory distress syndrome in pregnancy are discussed. (AM J OBSTET GYNECOL 1991;165:41-2.)

Key words: Adult respiratory distress syndrome, pulmonary embolism

Adult respiratory distress syndrome describes sudden respiratory failure as a result of noncardiogenic pulmonary edema.[1] Adult respiratory distress syndrome represents a final common pathway of lung injury because of a wide spectrum of unrelated causes resulting in increased alveolar-capillary permeability. Adult respiratory distress syndrome is characterized by progressive respiratory distress, severe hypoxemia relatively refractory to high inspired oxygen tension, low lung compliance, and diffuse infiltrates on chest roentgenogram, and carries a high mortality rate of between 50% to 80%.[2] This syndrome has been well documented in association with massive trauma and shock.[1] Over the past decade, adult respiratory distress syndrome has also been recognized in pregnancy.[1, 2] We present a rare case of extensive pulmonary embolism presenting as severe adult respiratory distress syndrome in a woman after surgical resection of a cornual pregnancy at 10 weeks' gestation in the absence of shock.

Case report

A 32-year-old, gravida 4, para 2 woman was first seen with abdominal pain in the right lower quadrant and irregular vaginal bleeding. On physical examination she was hemodynamically stable; blood pressure was 102/58 mm Hg and pulse was 82 beats/min. The abdomen was tender with no signs of peritoneal irritation. On pelvic examination the uterus were boggy and enlarged to 6 weeks' size and the right adnexa were tender with no palpable mass. Laboratory study results were within normal limits with a hematocrit value of 32%. A urine β-human chorionic gonadotropin test result was positive. Sonographic examination showed a gestational sac that measured 4.5 × 4.4 cm and contained a fetal pole with no fetal heart motion located in the right cornual area of the uterus. Laparoscopy confirmed the diagnosis of a cornual pregnancy and at laparotomy right cornual resection with right salpingectomy was performed. Twelve hours after surgery a hematocrit value of 20% was noted. Sonography revealed free fluid in the abdomen. The patient was transfused with 2 units of blood and at exploratory laparotomy the uterine incision, which was found to be bleeding, was sutured. Six hundred milliliters of clotted blood was removed from the abdomen. Two additional units of blood were transfused. The patient remained hemodynamically stable throughout surgery and platelet counts and coagulation study results were normal. The first 30 hours after the second surgical intervention were uneventful. Shortly thereafter the patient began to show signs of anxiety. At that time vital signs were stable. However, 15 minutes later she was noted to be unresponsive with profuse sputum production. Blood pressure was 108/64 mm Hg and pulse was 88 beats/min. Electrocardiogram revealed normal sinus rhythm with no abnormalities. Arterial blood gas showed pH 7.19, Pco_2 55 mm Hg, Po_2 9 mm Hg, oxygen saturation 6%. An immediate repeat analysis was similar (7.15, 60, 18, 22%, respectively). The patient was intubated and 100% oxygen administered. Chest roentgenogram revealed diffuse pulmonary infiltrates

throughout both lungs (Fig. 1). With the diagnosis of adult respiratory distress syndrome, she was transferred to the Surgical Intensive Care Unit, where she was paralyzed and ventilated (settings: FIO_2 100%, positive end-expiratory pressure 15 mm H_2O, intermittent mandatory ventilation 16/min, tidal volume 800 ml). A Swan-Ganz catheter was placed with the following pressures: right atrium 16 mm Hg, pulmonary artery 45/30 mm Hg, wedge 15 mm Hg, cardiac output 7.8 L/min, cardiac index 4.2, systemic vascular resistance 749 dyne · sec · cm^{-5}, ruling out a cardiac cause for this clinical presentation.

Subsequently, a ventilation perfusion scan showed multiple pulmonary emboli. Intravenous heparin therapy was initiated. Bilateral lower extremity color duplex venous scans were normal. Multiple cultures obtained from blood, sputum, and urine were negative. Thirteen days after the initial respiratory event, after gradually being weaned off the ventilator, the patient was extubated and Coumadin anticoagulant therapy was initiated. Three days later, the patient was discharged in good health with no signs of residual brain damage.

Comment

Among the multiple disorders associated with adult respiratory distress syndrome, the most common are sepsis, gastric aspiration, massive trauma, fat embolism, pneumonia, and disseminated intravascular coagulation.[1] Although documented in pregnancy in conjunction with preeclampsia, eclampsia, amniotic fluid embolism, fetal death in utero, abruptio placentae, chorioamnionitis, sickle cell crisis, trophoblastic disease, and pyelonephritis, the most common cause of adult RDS in pregnancy is that associated with tocolysis.[1] This has been noted to occur after administration of terbutaline sulfate, ritodrine, isoxsuprine hydrochloride, and fenestrel, especially with aggressive intravenous hydration.[1] In our case, severe adult respiratory distress syndrome was apparently caused by extensive pulmonary embolism in the absence of hemorrhagic shock, sepsis, diffuse intravascular coagulation or overhydration. Survival without brain damage despite a PO_2 of 9 mm Hg is remarkable. When presented with dyspnea, tachypnea, and progressive hypoxemia even in the absence of classic underlying causes, the obstetrician-gynecologist should be alert to the possibility of adult respiratory distress syndrome. Rapid diagnosis and immediate treatment with positive end-expiratory pressure ventilation, preferably with multidisciplinary assistance in conjunction with treatment of the underlying disease, will clearly benefit these critically ill patients.

Ten years after cryosurgical treatment of cervical intraepithelial neoplasia

John Dræby-Kristiansen, MD, Michael Garsaae, MD, Morten Bruun, MD, and Kristen Hansen, MD
Herning, Denmark

From 1974 to 1977 we treated 96 patients for grade 2 or 3 cervical intraepithelial neoplasia with cryotherapy. They were monitored for 10 to 14 years with an attendance rate of 98%. Treatment resulted in cure in 92%. Nine patients had persisting lesions, and three patients had a recurrent lesion. The last recurrence was diagnosed 6.7 years after cryotherapy. (Am J Obstet Gynecol 1991;165:43-5.)

Key words: Cryosurgery, cervical intraepithelial neoplasia, long-term follow-up

The prevalence of cervical intraepithelial neoplasia has more than doubled during the last decade and has now reached 18.8 per thousand among teenagers.[1] Cryotherapy was introduced late in the 1960s as a less destructive treatment than surgical conization.[2] Invasive cervical cancer takes about 10 years to develop from cervical intraepithelial neoplasia[3]; therefore it is possible to assess the efficacy of cryotherapy only after this period. We have monitored 96 patients for at least 10 years after cryotherapy grade 2 or 3 cervical intraepithelial neoplasia.

Material and methods

Ninety-six patients were diagnosed as having grade 2 or 3 cervical intraepithelial neoplasia from 1974 to 1977 and were treated by cryotherapy. They all had a visible transformation zone, and endocervical curettage displayed no cervical intraepithelial neoplasia. The actual age distribution and grade of cervical intraepithelial neoplasia are given in Table I.

Nitrous oxide was used as the cryogenic for cryotherapy. The diameter of the cone-shaped cryoprobe was 19 mm, and the height of the conus was 16 mm. The probe was applied for two 3-minute periods. For patients 1 through 25 the pause was 1 to 3 months. For the remaining patients the pause was 5 minutes.

After cryocoagulation, cytologic examination was carried out four times during the first year, twice during the second year, and thereafter once a year. After the fifth year the cytologic controls were done by the patient's own general practitioner.

Colposcopic examination was routinely performed after 3 months; 1, 3, and 5 years; and when indicated by cytologic testing.

The result of each woman's most recent smear test was obtained from her general practitioner. If the latest smear test was performed <10 years after cryotherapy, the patient was referred for cytologic control.

If cervical intraepithelial neoplasia was diagnosed

10-11	0	66	87.4	79.9-94.9

*Number in parentheses represents number of patients treated by recryocoagulation.

during the first year after cryotherapy, the lesion was defined as persisting. If this diagnosis was obtained later in the study period, the lesion was defined as recurrent. Treatment by recryocoagulation was accepted in all cases.

Statistical calculations were based on Fischer's test, with a significance level of $p < 0.05$.

Results

After the first cryotherapy nine patients had a persisting lesion. After recryocoagulation, six still had a persisting lesion; three of them were treated with conization and three with hysterectomy. There was no significant difference ($p = 0.703$) between grade 2 and grade 3 cervical intraepithelial neoplasia (Table I).

Follow-up for 10 years failed in seven patients. Two did not volunteer in the control program; however, the most recent smears obtained from these patients (67 and 82 months, respectively) after the cryotherapy were normal. Five patients had hysterectomy for reasons other than cervical intraepithelial neoplasia (the average time of control for these patients was 62 months), and they were all shown to have normal histologic features of the cervix.

One patient had persisting lesions despite undergoing cryotherapy three times. She refused to undergo conization, and a lethal invasive cervical cancer developed 3.6 years after the first cryocoagulation.

Three other patients had a recurrent lesion after 3, 3.7, and 6.7 years, respectively (Table II). One of these patients was treated by recryocoagulation and two underwent hysterectomy (Fig. 1).

Comment

A 92% effectiveness after cryotherapy of grade 2 or 3 cervical intraepithelial neoplasia is in agreement with other studies,[4-7] despite the fact that these studies have a lower attendance for follow-up than the 98% (2/96) in this investigation. Most of the treatment failures were persisting dysplasia (9/12, 75%). Only three showed recurrent dysplasia. Therefore follow-up with intensive control during the first year after cryotreatment is strongly recommended.

Treatment of grade 2 and 3 cervical intraepithelial neoplasia was equally successful. This is in agreement with Townsend and Richart,[8] who found that the effectiveness of cryotherapy is dependent on the area of the lesion and not the degree.

Overlooked invasive growth at the time of treatment is the most frequent reason for the apparent development of cervical cancer after cryotherapy.[9, 10] We underscore the importance of colposcopic examination, endocervical curettage, and colposcopically directed cervical biopsy of the most advanced lesions.

The observed failure rate of 13% (12/96) in this study and up to 20% in other studies[10] and the possibility of developing cervical cancer, documented both in this study and in others,[11-13] emphasize the necessity of being absolutely sure that the patients to whom we offered cryotherapy agreed to the follow-up controls.

In conclusion, cryotherapy is economical and gentle and can be done on an outpatient basis without anesthesia. We find cryotherapy to be as effective for the treatment of cervical intraepithelial neoplasia as electrocauterization and the more expensive and laborious laser therapy.[8, 14-16]

Recurrence of ectopic pregnancy: The role of salpingitis

**M. Riduan Joesoef, MD, PhD,[a] L. Westrom, MD,[b] G. Reynolds, PhD,[a]
P. Marchbanks, PhD,[a] and W. Cates, MD, MPH[a]**
Atlanta, Georgia, and Lund, Sweden

We evaluated the role of salpingitis on the recurrence of ectopic pregnancy from a historical cohort of 2501 women who had undergone laparoscopic examination for acute salpingitis. We used pregnancy ($N = 2899$) as the unit of analysis and a modified conditional logistic regression to estimate a pairwise odds ratio as a measure of the recurrence of ectopic pregnancy. Among the second or higher order of pregnancy, the recurrence was 21.7%. For pregnancies with a prior uterine pregnancy, the ectopic pregnancy rate increased with prior salpingitis scores constructed from a combination of prior salpingitis episodes and severity (0 score, 2.7%; 1 to 2 scores, 4.8%; and ≥ 3 scores, 12.1%). For those with a prior ectopic pregnancy, the rate did not increase with prior salpingitis scores (score 0, 20.0%; score 1 or 2, 19.2%; and score ≥ 3, 26.9%). The adjusted pairwise odds ratio was 2.2 and was practically unchanged (2.1) after additional adjustment with prior salpingitis scores. These findings confirm salpingitis as a risk factor for first ectopic pregnancy, but once a woman had an ectopic pregnancy, previous salpingitis might not add any incremental risk. (Am J Obstet Gynecol 1991;165:46-50.)

Key words: Salpingitis, ectopic pregnancy

Ectopic pregnancy, a sequel of pelvic inflammatory disease, has increased worldwide.[1] Ectopic implantation not only affects the current pregnancy, but also is associated with recurrence in subsequent pregnancies. The estimated recurrence rate of ectopic pregnancy ranges from 10% to 20%.[2-4] A number of case control studies have reported an increased risk of ectopic pregnancy for those with a prior history of this condition, with odds ratios ranging up to ninefold.[5, 6] While previous cohort studies have documented a strong association between earlier salpingitis episodes and the initial ectopic pregnancy,[7, 8] no studies have investigated the combined role of previous salpingitis and ectopic pregnancy on the recurrence of ectopic pregnancy. In this study, we evaluated the role of salpingitis before and after the initial ectopic pregnancy on the recurrence of ectopic pregnancy from a large historic cohort study, with pregnancy used as the unit of analysis.

Material and methods

The study population consisted of a cohort of 2503 women, <36 years old, who underwent a laparoscopic examination at the Department of Obstetrics and Gynecology, University Hospital, Lund, Sweden, from Jan. 1, 1960, through Dec. 31, 1984. Briefly, the University Hospital is the only hospital in the city of Lund for inpatient treatment of gynecologic disorders. It served a female population (age 10 to 35 years) ranging from approximately 40,000 in 1960 to 50,000 in 1984. All women in this study were inpatients with signs and symptoms of acute pelvic inflammatory disease who underwent index (initial) laparoscopy within 24 hours of admission. For each woman a thorough review of her fertility status after initial laparoscopy was conducted up to Dec. 31, 1984. The findings of laparoscopy were graded as follows: normal, no abnormality in the pelvic cavity; mild salpingitis, fallopian tubes reddened and swollen but freely movable with normal morphologic characteristics of fimbriated ends; moderately severe salpingitis, more advanced inflammatory changes with tubes not freely movable and abnormal or not clearly visible fimbriated ends; severe salpingitis, pelvic peritonitis or abscess formation with visibility significantly impaired by inflammatory masses (ostia were not visible).

Of the 2503 women, two were excluded because of insufficient information on date of initial laparoscopy. Of these 2501 women, 206 did not undergo complete follow-up, 19 had a history of ectopic pregnancy before initial laparoscopy, and 736 never became pregnant after initial laparoscopy (Fig. 1). The interval of follow-up for women in this cohort ranged from 1 to 315 months. Of the 1540 women who became pregnant after initial laparoscopy, 754 had been pregnant once, 403 twice, 248 three times, 93 four times, and 42 more than four times. Two pregnancies were excluded from the analysis because of insufficient information in

the records. A total of 2899 pregnancies were included in this analysis—1538 first-order, 786 second-order, 383 third-order, and 192 fourth-order or higher pregnancies.

Our main objective was to evaluate the role of salpingitis before and after the initial ectopic pregnancy on the recurrence of ectopic pregnancy. Because the unit of analysis is pregnancy and the pregnancy outcomes in a woman are not independent (the basic assumption of classic logistic regression), we used a modified conditional logistic regression model[9] to adjust for other known risk factors for ectopic pregnancy. This model computes both the adjusted odds ratios for risk factors and a pairwise odds ratio as a measure of the recurrence of ectopic pregnancy.

Each pregnancy could have been preceded by none, one, or several episodes of salpingitis, which had varying degrees of severity. We constructed a salpingitis score that took into account the number of salpingitis episodes and their severity (no salpingitis, score of 0; mild salpingitis, 1; moderate, 2; severe, 3). We then summed the scores for all episodes of salpingitis. For example, a pregnancy that had three prior episodes of salpingitis (mild, severe, and severe) would have a score of 7 (1 + 3 + 3). The salpingitis scores for the pregnancies ranged from 0 to 9.

For each pregnancy we evaluated and adjusted the analysis for the following risk factors: age at pregnancy (<25, 25 to 30, or >30 years), marital status (single, married, or others), number of prior pregnancies (0,

1, 2, or >2), prior salpingitis scores (score 0, 1 to 2, 3, or >3), and number of prior adnexal operations (0, 1, or >1). Such operations were mostly salpingostomy, salpingectomy, or salpingo-oophorectomy because of prior ectopic pregnancy. The microbiologic organisms in the salpingitis episodes could not be evaluated because routine testing for chlamydial infection was not started until 1977. Thus small numbers limited the power to differentiate gonococcal from chlamydial or other infectious causes of salpingitis.

Results

Of the 2899 pregnancies, 193 (6.7%) were ectopic pregnancies (Table I). The proportion of ectopic pregnancies increased significantly with age at pregnancy, prior salpingitis episodes, and salpingitis score (Table I). A stronger trend was found for prior adnexal operations. In addition, the proportion of ectopic pregnancies among women with no or one episode of salpingitis increased significantly with salpingitis severity (no previous salpingitis, 2.2%; mild previous salpingitis, 5.0%; moderate salpingitis, 7.7%; and severe salpingitis, 14.1%).

Of the 1538 first-order pregnancies, 104 (6.8%) were ectopic (Table II). Among second-order or higher pregnancies, 5.6% were ectopic for those with a prior uterine pregnancy, and 21.7% for those with a prior ectopic pregnancy. The risk of ectopic pregnancy increased significantly with prior salpingitis scores for first-order pregnancies and for second-order or higher pregnancies with a prior uterine pregnancy. However, the risk of subsequent ectopic pregnancy did not increase significantly with prior salpingitis scores for those with a prior ectopic pregnancy.

Except for those pregnancies occurring after a prior ectopic pregnancy, we found a statistically significant ($p < 0.01$) increase in odds ratios of ectopic pregnancy with increasing salpingitis scores (Table II). When those with score 0 are taken as a reference group, the adjusted odds ratios for scores 1 to 2 and ≥3 were 5.0 and 12.9 for first pregnancy, 1.7 and 3.9 for pregnancies with a prior uterine pregnancy, and 0.7 and 1.2 for pregnancies with a prior ectopic pregnancy, respectively. We were unable to evaluate the effect of additional salpingitis after the initial ectopic pregnancy for recurrent ectopic pregnancy because the number of such cases was too small (one case).

The pairwise odds ratio for recurrent risk of ectopic pregnancy adjusted for marital status, age at pregnancy, number of prior pregnancies, and number of adnexal operations was 2.2 (95% confidence interval, 1.6 to 3.1); it was practically unchanged at 2.1 (95% confidence interval, 1.4 to 3.0) after additional adjustment with prior salpingitis scores (data not shown). The pairwise odds ratio 2.1 means that on average the odds of a subsequent ectopic pregnancy increased 2.1 times if the prior pregnancy was ectopic (after adjustment for all the mentioned variables).

Comment

This study indicates that once a woman has had an ectopic pregnancy, her odds of having another ectopic pregnancy are doubled. Thus the risk of ectopic pregnancy as a sequela of salpingitis persists beyond the first episode. Although prior salpingitis is an important risk factor for first ectopic pregnancy (as indicated by increased adjusted odds ratios up to 12.9 for first ectopic pregnancy), it may not add incremental risks for recurrence (as indicated by low adjusted odds ratios up to 1.2 for recurrence of ectopic pregnancy). These findings emphasize the chronicity and serious nature of salpingitis once it causes an ectopic pregnancy.

The surgical treatment for the initial ectopic pregnancy may mask the effect of prior salpingitis for the subsequent ectopic pregnancy. To take into account such an effect of the surgical treatment, we conducted

†Adjusted for marital status, age at pregnancy, number of prior adnexal operations, and number of prior pregnancies.

the following analyses. First, we adjusted the analysis with the surgical treatment (as had been shown in Table II) and conducted a separate analysis excluding those with one tube removed during the surgical treatment. Both analyses produced similar results. Second, we conducted a separate analysis excluding those with recurrent ectopic pregnancy affecting the same tube as in the previous ectopic pregnancy. We suspect that the recurrent ectopic pregnancies of the same tube may be due mainly to the surgical treatment. We found among the second-order or higher pregnancies that the proportion of recurrent ectopic pregnancy slightly increased (but not significantly so, at $p = 0.05$) to correspond with prior salpingitis score (11.1% [1/9] for a score of 0, 10.0% [4/36] for a score of 1 to 2, and 15.0% [3/17] for a score of ≥3). Because of the small number of recurrent ectopic pregnancies in this population (18 cases) and the uncertainty of the carryover effect of salpingitis on the tube operated on, we should interpret these findings cautiously. Unfortunately, we were unable to evaluate the effect of additional salpingitis after the initial ectopic pregnancy because of the small number of such cases.

Biologically, the tubal damage resulting from salpingitis appears irreversible. If serious enough to cause an initial ectopic pregnancy, the same intraluminal adhesions or dysfunction remains to threaten any subsequent pregnancy. Different mechanisms may account for the tubal damage caused by either gonococcal or chlamydial infections. With gonorrhea, an endogenous tumor necrosis factor[10] or interferon gamma may be involved.[11] With chlamydia, immune-mediated tubal destruction may be stimulated by repeat infections.[12] Regardless of the precise pathophysiologic basis, the postinfection intraluminal scarring has long-lasting effects.

To our knowledge, this study is the first to document the role of salpingitis in recurrence of ectopic pregnancy, with an appropriate multivariate analysis. Previous studies were mostly based on a case-control design with the woman as the unit of observation.[1] One follow-up study of 110 patients attempting pregnancy after ectopic pregnancy showed similar results—no association between recurrent ectopic pregnancy and previous history of pelvic inflammatory disease.[4] This study, a large historic cohort study, used pregnancy, the ideal denominator for ectopic pregnancy, as the unit of observation. Unlike others, our study estimated the pairwise odds ratio, a desirable measure of association for recurrent effect of ectopic pregnancy, and adjusted this odds ratio for a set of known risk factors.

We initially adjusted the analysis for use of intrauterine contraceptive device (yes/no) and found similar results. However, we felt the information was not adequate because this information was obtained only at initial laparoscopy, not during the follow-up period. Women might use or discontinue the intrauterine contraceptive device shortly after the initial laparoscopy. Because of this uncertainty and because of similar results after adjustment for use of intrauterine contraceptive device we presented the final analysis without the adjustment for intrauterine contraceptive device use. We did not adjust the analysis for prior infertility because this information was not asked before each pregnancy (unit of analysis). However, we adjusted the analysis for two factors as surrogates for prior infertility—prior salpingitis score (an indicator of tubal patency and a strong predictor of infertility) and previous pregnancies.

Our findings on the association between previous salpingitis episodes and ectopic pregnancy confirm the previous study that used the same but smaller data set.[7,8] A population-based case-control study reported an odds ratio of 3.3 between ectopic pregnancy and history of pelvic inflammatory disease.[13] Other studies also documented similar results.[5,6] The recurrence of ectopic pregnancy reported in this study is similar to that found in other studies.[4-6]

Our data underscore the importance of public health programs in preventing the first ectopic pregnancy from occurring. As the incidence of ectopic pregnancy is increasing, the proportion of recurrent ectopic pregnancies will undoubtedly also increase. Programs to prevent sexually transmitted lower genital tract infections, specifically those causing pelvic inflammatory disease, must play a major role in stopping the chain reaction among salpingitis, first ectopic pregnancy, and recurrent ectopic pregnancy.

The prevalence of autoantibodies during third-trimester pregnancy complicated by hypertension or idiopathic fetal growth retardation

J. Milliez, MD,[a] F. Lelong, MD,[b] N. Bayani, MD,[b] D. Jannet, MD,[a] M. El Medjadji, MD,[a] H. Latrous, MD,[a] M. Hammami, MD,[a] and B.J. Paniel, MD[a]
Creteil, France

Lupus anticoagulant, anticardiolipin, antinuclear, anti–deoxyribonucleic acid, antithyroglobulin, and antithyroid microsomal antibodies were assayed during third-trimester pregnancy (100 normal, 100 with complications). In spite of a normal activated partial thromboplastin time in all instances, lupus anticoagulant was further investigated by three additional procedures: tissue thromboplastin inhibition time, platelet neutralization procedure, and cephalin neutralization test. The prevalence of autoantibodies in pregnancies with hypertension reaches 16% (four with lupus anticoagulant, two with anticardiolipin, and two with antithyroid microsomal antibodies), which is significantly greater than that for idiopathic fetal growth retardation (2%) (one with lupus anticoagulant antibodies) and normal pregnancies (3%) (two with antithyroglobulin and one with autithyroid microsomal antibodies) ($p < 0.01$). Autoantibodies were equally distributed between patients with gestational hypertension and those with preeclampsia. When compared with the 42 patients with hypertension and no autoantibodies, the eight patients with autoantibody had a more frequent history of fetal growth retardation ($p < 0.05$), but there was no difference in the severity of hypertension, the frequency of obstetric complications, or the outcome of pregnancy. They did not require any specific treatment. (Am J Obstet Gynecol 1991;165:51-6.)

Key words: Autoantibodies, antiphospholipids, hypertension in pregnancy

Antiphospholipid antibodies, the lupus anticoagulant and anticardiolipin antibodies, may be responsible for major complications of pregnancy; such as repeated early abortion,[1] second-trimester intrauterine fetal death, severe fetal growth retardation, and preeclampsia.[2-4] Antiphospholipid antibodies are often associated with organ-specific autoantibodies, and a reproductive autoimmune failure syndrome has been described.[5]

The prevalence of these autoantibodies has been well documented in normal pregnant women[6-8] and in pregnant women with early onset severe hypertension[9] but not during pregnancy complicated by gestational hypertension or idiopathic fetal growth retardation. The aim of this study was to evaluate the prevalence of antiphospholipid and other specific autoantibodies in pregnancies complicated by hypertension or idiopathic fetal growth retardation and to compare it with the prevalence of these autoantibodies in a general obstetric population.

Population and methods

Patients. Two hundred pregnant patients were screened for the presence of autoantibodies. The investigation was approved by the local Human Investigation Committee and informed consent was obtained from each patient. None of the patients had systemic lupus erythematosus or any other documented autoimmune disease such as sclerodermia, myasthenia, autoimmune thrombocytopenic purpura, or a history of thromboembolic disease. None of them was receiving chlorpromazine, which is known to induce lupus-like anticoagulants and autoantibodies.[10] All blood samples were taken during the third trimester of pregnancy, thereby excluding from the study early abortions and second-trimester intrauterine fetal deaths.

Normal pregnancies. One hundred patients without complications of pregnancy were enrolled during the period of the study from our antenatal clinic, and these formed the control population. All had normal pregnancies and none was receiving any registered medication.

Pregnancies complicated by idiopathic fetal growth retardation. Fifty patients had fetal growth retardation diagnosed during pregnancy by clinical examination and echography. Twenty-eight neonates had birth weight below the 10th percentile and 22 neonates had

birth weight below the 3rd percentile. All patients had normal blood pressure. Three patients were taking 150 mg of aspirin daily (Juvépirine; Sarget, Mérignac, France) because of a history of severe fetal growth retardation during the previous pregnancy.

Pregnancies complicated by hypertension. In 50 patients high blood pressure developed during pregnancy. Twenty of these patients had moderate gestational hypertension (diastolic blood pressure <120 mm Hg),[11] five had severe gestational hypertension (diastolic blood pressure >120 mm Hg), 10 had late-onset moderate preeclampsia, five had early onset severe preeclampsia, two had superimposed preeclampsia, and eight had chronic hypertension, which was brought under control 3 months after delivery. All patients were on a regimen of oral antihypertensives: 26 received atenolol (Tenormine; Ici Pharma, Cergy, France), 10 were receiving methyldopa (Aldomet; Merck Sharp & Dohme Chibret, Paris), seven were receiving dihydralazine (Nepressol; Ciba-Geigy, Rueil-Malmaison, France), and one was taking clonidine (Catapressan; Boehringer-Ingelheim, Reims, France). Six patients were taking 150 mg of aspirin daily (Juvepirine; Sarget, Merignac, France) because of a history of severe hypertension during the previous pregnancy.

Clinical features and outcomes of pregnancy were compared in the two study populations and the control series (Table I). The medical histories of the multiparous women during the previous pregnancies were compared.

Methods

The 200 pregnant patients had standard coagulation tests, including prothrombin time, kaolin clotting time (activated partial thromboplastin time with kaolin as activator), thrombin time, assay of fibrinogen, antithrombin III activity and antigen, and protein C activity and antigen. Functional assay of antithrombin III and protein C was performed with specific chromogenic substrates (AT Prest and Stachrom Protein C-Stago; Diagnostica Stago, Asnières, France); an immunologic dosage of antithrombin III was given by laser nephelometry (Behring Diagnostic, Rueil-Malmaison, France).

Lupus anticoagulant. Antithromboplastin circulating anticoagulants were investigated, even when standard coagulation tests proved normal, by three additional procedures.

Tissue thromboplastin inhibition time. As described by Schleider et al.,[12] this test is based on the principle that antithromboplastin antibodies are more easily detected at low concentrations of phospholipids. The test was conducted with increasing dilutions of thromboplastin, from 1 : 100 to 1 : 4000. The ratio of the patient's plasma clotting time to the control plasma clotting time at a 1 : 100 dilution of thromboplastin was considered as abnormal when it exceeded 1.3.

Platelet neutralization procedure of Triplett et al.[13] This test implies adsorption of the patient's circulating anticoagulant by a platelet suspension. Shorter kaolin clotting time after adsorption compared with initial kaolin clotting time and a saline solution control, suggests the presence of a lupus-like inhibitor. Time reduction depends on the potency of the circulating anticoagulant; it was considered as significant if it exceeded 10 seconds when compared with initial kaolin clotting time.

Standard and high phospholipid concentration activated partial thromboplastin time. This procedure depends greatly on the detection of antithromboplastin antibodies in the reagent used. We used Platelin (Organon Teknika, Fresnes, France) as the source of phospholipids. This test is based on attenuation of the anticoagulant effect of antiphospholipid antibodies when phospholipids are added in excess. The ratio of the patient's clotting time to the control clotting time was established for two concentrations of platelin, a standard and a high concentration. The test result was considered positive when the patient/control ratio for the high concentration was lower than the patient/control ratio for the standard concentration and when the difference was >0.17.[14]

Anticardiolipin antibodies. Anticardiolipin antibodies were screened by the immunoenzymatic technique of Loizou et al.[15] For each serum sample the results were expressed as optical density corrected by comparison with an intralaboratory standard, tested during each procedure. A positive value was defined as an optical density absorbance >5 SD above the mean control value obtained in 107 normal subjects (107 blood donnors included as a control group).

The mean of this control group was estimated to be 0.11 optical density units (optical densities from 0.00 to 0.283), with a standard deviation of 0.07. Therefore, the value of the mean + 5 SD being 0.460 optical density units, the threshold of positivity for the study group was established at an optical density of 0.500 optical density units. All elevated samples underwent repeat testing and were checked against the standard serum of Harris and Hugues,[16] with a threshold of positivity above 15 GPL units (immunoglobulin G antiphospholipid units).

Autoantibody assays. Various antoantibodies against specific cell components were investigated.

Antinuclear antibodies were assayed by indirect immunofluorescence on slices of rat liver and smears of HEp2 cells. The different dilutions were incubated with substrate for 30 mintues at room temperature. The second antibody used was a fluorescein-conjugated goat polyvalent antiimmunoglobulin (anti-IgG, anti-IgA, anti-IgM, anti-κ, and anti-λ) (Institut Pasteur Production, Marne La Coquette, France). The results were given in serum dilutions. The threshold for positivity was established at 1:50, and any positive serum was then titrated by successive dilutions until extinction of fluorescence.

Anti–deoxyribonucleic acid antibodies were evaluated by indirect immunofluorescence on *Crithidia luciliae* cultures. Sera diluted 1:10 in phosphate buffer were incubated with substrate for 30 minutes at room temperature. A second fluorescein-conjugated goat polyvalent antibody (Institut Pasteur Production) allowed the detection of anti–deoxyribonucleic acid antibodies.

Antithyroglobulin antibodies were screened by passive hemagglutination (Thymune T; Wellcome, Paris). Antithyroid microsomal antibodies were assayed by passive hemagglutination (Thymune M; Wellcome).

Antiphospholipid antibodies may induce thrombocytopenia[2, 4] and false-positive syphilitic reactions[4]; platelet count was checked in all instances, and standard tests for syphilis (Venereal Disease Research Laboratory and *Treponema pallidum* hemagglutination) were done.

Statistical analysis. Variables between series were compared by the χ^2 test or by Yates' χ^2–derived test when the sample size was <5. Comparison of the means was done by analysis of variance. Results were expressed as means with standard deviations. Differences were considered as statistically significant for a p value <0.05.

Table II. Prevalence of autoantibodies

Lupus anticoagulant	4	1	0
Anticardiolipin antibodies	2	0	0
Anti–cell component antibodies	2	0	3
TOTAL	16%*	2%	3%

*$p < 0.01$, compared with other two groups.

Results

Standard coagulation tests. Results of all 200 standard coagulation tests were normal, and no kaolin clotting time was >7 seconds above control, thereby eliminating the presence of frank lupus anticoagulant.

The prevalence of lupus anticoagulant, antiphospholipid antibodies, and cell component–specific autoantibodies is depicted in Table II for each series of patients.

Normal pregnancies. Among the 100 normal pregnancies, no lupus anticoagulant or anticardiolipin antibodies were found. The values obtained for anticardiolipin antibodies in this group of 100 normal pregnant women were equivalent to those established within the control group of 107 blood donors: a mean of 0.11 optical density units (for optical densities from 0.02 to 0.290) with a standard deviation of 0.07. Specific autoantibodies against cell components were detected in three patients: two had antithyroglobulin antibody at a dilution of 1:80 and one had antithyroid microsomal antibody at a dilution of 1:40.

Idiopathic fetal growth retardation. Of 50 patients with a growth-retarded fetus, none had anticardiolipin antibody or autoantibody against cell components. One patient with a small-for-gestational-age infant <3rd percentile had normal blood pressure, did not take aspirin, and had a false-positive syphilitic reaction. A lupus anticoagulant was detected by all three procedures (tissue thromboplastin inhibition time, at a dilution of 1:100, ratio of patient's clotting time/control clotting time of 1.48; platelet neutralization procedure, kaolin clotting times of 48.5 seconds initially and 35 seconds after platelet neutralization [saline solution control 43 seconds]; platelin neutralization test, standard – high ratio = 0.78).

Hypertension during pregnancy. Among the 50 pregnant patients with hypertension, eight had autoantibodies. Lupus anticoagulant was detected in four patients. One had positive results for all three proce-

Table III. Comparison of pregnancies with hypertension ($n = 50$) according to presence of autoantibodies

	Autoantibodies ($n = 8$)	*No autoantibodies ($n = 42$)*	*Significance*
Age (yr)	28 ± 5.3	29.4 ± 5.6	NS
Parity	2.6 ± 1.2	2.9 ± 1.3	NS
Birth weight (gm)	2670 ± 715	2548 ± 640	NS
Gestation at delivery (wk)	38.4 ± 1.9	39.6 ± 2.1	NS
Birth weight <10th percentile (No.)	3 (37%)	17 (40%)	NS
Birth weight <3rd percentile (No.)	0	8 (20%)	NS
Platelet count (No./mm^3)	286.000	283.000	NS

dures. For tissue thromboplastin inhibition, at a dilution of 1 : 100, the ratio of patient clotting time/control clotting time was 1.40. For the platelet neutralization procedure, initial kaolin clotting time was 39 seconds; after platelet neutralization it was 28 seconds; saline solution control was 37 seconds. For platelin neutralization test, difference standard − high ratio = 0.28. One patient had a positive platelet neutralization procedure (kaolin clotting time: initial, 47 seconds; after platelet neutralization, 37 seconds; saline solution control, 46 seconds). Two patients had positive results only for the platelin neutralization test (standard − high ratios of 0.35 and 0.40, respectively). All results were checked twice.

Anticardiolipin antibody was detected in two patients with optical density values of 0.600 and 0.733 optical density units, respectively. These results were duplicated for confirmation. The values found by checking against the standard serum of Harris and Hugues[16] were 17 and 20 GPL units, respectively.

Autoantibodies against cell components were found in three patients, two with antithyroid microsomal antibody ratios of 1 : 400 and 1 : 600, respectively, and one with weak antinuclear antibody dilution of 1 : 50.

The latter patient was one of the four with lupus anticoagulant; therefore a total of eight patients (16%) had autoantibodies detected among the pregnant patients with hypertension, including six (12%) with antiphospholipid antibodies. Both figures are significantly increased as compared with results in the control pregnant patients and the group with idiopathic fetal growth retardation ($p < 0.01$) (Table III).

Autoantibodies were equally distributed between patients with gestational hypertension (one with lupus anticoagulant, two with anticardiolipin antibodies, and one with antithyroid microsomal antibody) and those with preeclampsia (three with lupus anticoagulant and one with antithyroid microsomal antibody) (Table IV). The frequency of preeclampsia, gestational hypertension, and chronic hypertension, whether moderate or severe, was not different among the eight patients with hypertension and autoantibodies and the other 42 patients with hypertension but without autoantibodies (Table IV). The outcome of pregnancy also did not differ among the patients (Table III). The eight patients with hypertension and autoantibodies were multiparous, and the history of their previous pregnancies was compared with that of the 28 multiparous women with hypertension and autoimmune anomalies. A significantly more frequent occurrence of fetal growth retardation during previous pregnancies was recorded among patients with hypertension and autoantibodies (6/8 or 75% vs 8/28 or 28%, $p < 0.05$). A more frequent history of two or more spontaneous abortions also was noticed for these patients but the difference did not reach statistical significance (3/8 or 37% vs 4/28 or 14%, difference not significant).

None of the six patients with hypertension who received aspirin showed alterations in results of the coagulation tests. One patient receiving dihydralazine had lupus anticoagulant detected by the platelet neutralization procedure, but she did not have antinuclear or anti–deoxyribonucleic acid antibody. Six other patients receiving dihydralazine had no biologic autoimmune anomaly.

Comment

Although they act in vitro as anticoagulants, antiphospholipid antibodies induce in vivo procoagulant effects, interfering with the phospholipid antigens of prothrombin activators (activated factor X, factor V, and phospholipids).[2] More than 90% of patients with lupus anticoagulant also have anticardiolipin antibodies.[9] Despite recent evidence against their prostaglandin-mediated effects on cultured endothelium,[17] it has been suggested that antiphospholipid antibodies prevent prostacyclin production and cause hypertension.[18] They also bind to phospholipid antigens of the placental vessels, inducing placental infarction and fetal growth retardation or even fetal death.[1, 2, 19] Immunoglobulin G fractions from patients with antiphospholipid antibodies cause decidual necrosis and fetal death in mice.[20] Reproductive failures and obstetric complications have been well documented in patients with antiphospholipid antibodies,[1-4] and an antiphospholipid antibody syndrome has recently been proposed.[21]

In all previous studies[1-4, 6, 9, 22] lupus anticoagulant was

assayed only by activated partial thromboplastin time and standard coagulation tests. The difference with our study was that for our 200 patients the standard coagulation test results and the kaolin clotting time were always normal. The sensitivity of activated partial thromboplastin time varies widely according to the methods used or the laboratory. It is possible that our standard coagulation tests lacked sensitivity, but the kaolin clotting time is usually considered to be very sensitive for the detection of lupus anticoagulants. We deliberately looked for a lupus anticoagulant with three additional procedures (tissue thromboplastin inhibition time, platelet neutralization procedure, standard and high phospholipid concentration activated partial thromboplastin time) even when the kaolin clotting time was normal. We found lupus anticoagulant in five patients despite a normal kaolin clotting time (four with hypertension-complicated pregnancies and one with growth retardation); therefore these procedures may be even more sensitive and detect lower levels of lupus anticoagulant or involve antigens of different specificity than the kaolin clotting time.

Pregnancies complicated by antiphospholipid antibodies share several common features with preeclampsia[9]; in both, the placenta may show infarctions and decidual vasculopathy. Indeed, lupus anticoagulant is often associated with preeclampsia.[2, 3] Two studies on the prevalence of antiphospholipid antibodies among preeclamptic patients resulted in conflicting conclusions. Scott[22] found no association between anticardiolipin antibodies and preeclampsia (of unspecified severity) whereas Branch et al.[9] showed significant levels of antiphospholipid antibodies in 16% of women with early onset severe preeclampsia. We also found that 16% of women with hypertension-complicated pregnancies had autoantibodies (12% had antiphospholipid and 4% had antithyroid microsomal antibodies). However, our population with pregnancy complicated by hypertension was not restricted to preeclampsia; some of the patients had gestational or chronic hypertension. In our study autoantibodies were equally distributed between patients with gestational hypertension and those with preeclampsia with three patients in each group having antiphospholipid antibodies and one patient in each group having antithyroid microsomal antibody (Table IV). Therefore investigation for antiphospholipid antibodies should not be limited to preeclampsia. Gleicher and El-Roeiy[5] also were able to demonstrate increased autoantibody levels in hypertensive diseases of pregnancy in comparison with nonpregnant controls. We confirmed their findings with a significantly higher prevalence of autoantibodies in pregnancy complicated by hypertension (16%) as compared with normal pregnancy (3%) ($p < 0.01$). However, whereas lupus anticoagulant may be responsible for major complications of pregnancy[2-4] and thromboembolic accidents,[9] in our study antiphopholipid antibodies were not related to an aggravation of hypertension (Table IV), an impairment of fetal growth, or a poor fetal outcome (Table III) among women with pregnancy complicated by hypertension. Therefore a need for treatment with heparin was not apparent.[23]

Lupus anticoagulant can induce intrauterine fetal growth retardation.[2] In our study the prevalence of lupus anticoagulant among pregnancies complicated by idiopathic fetal growth retardation was only 2%. However, in pregnancy complicated by hypertension, patients with autoantibodies had a significantly more frequent history of fetal growth retardation during a previous pregnancy than patients with no autoantibody (75% vs 28%, $p < 0.05$). Therefore only patients with pregnancy complicated by hypertension and a history of fetal growth retardation should be screened for autoantibodies.

In a general obstetric population the lupus anticoagulant detected by standard coagulation tests has a prevalence of 0.27%,[6] and there was a similar prevalence of 0.3% in a series of 1000 women with a history of fetal death or thromboembolic disease who did not have systemic lupus erythematosus.[24] In a series of 43 women with normal pregnancy El-Roeiy et al.[8] did not find lupus anticoagulant. In our series of 100 control pregnant women we did not find lupus anticoagulant, but it is possible that a larger sample might have yielded a small prevalence comparable to the findings of the above studies.

Anticardiolipin antibodies in two different low-risk obstetric populations had a prevalence of 2.2%[6] and 2.1%,[25] respectively. Again we did not find anticardiolipin antibody in our control population. This discrepancy may arise from a difference in sensitivity between the method of Loizou et al.[15] that we used and the immunoenzymatic methods of the other studies.

Autoimmune disorders result from polyclonal B lymphocyte activation; autoantibodies against cell components, such as antinuclear, anti–deoxyribonucleic acid, antithyroglobulin, or antithyroid microsomal antibodies, are often associated with antiphospholipid antibodies in unexplained infertility or early pregnancy loss.[5, 26] Evaluation of such autoantibodies during pregnancy has yielded conflicting results. Patton et al.[7] found a very high figure of 40.5% with autoantibodies among 84 normal pregnancies, including 25% with antinuclear and antithyroid microsomal antibodies, which is at odds with our findings. Conversely, El-Roeiy et al.[8] found that the majority of autoantibody levels in pregnant women were within normal nonpregnant ranges and that alterations occur, if at all, at the time of delivery. We found a 3% prevalence of antithyroid antibodies in our women with normal pregnancy. The difference with the study by El-Roeiy et al.[8] is that our patients were screened only once and only during the third trimester of pregnancy; therefore the potential influence of delivery on the level of autoantibodies was not examined.

We conclude that tests for the detection of autoantibodies during pregnancy should preferentially be performed for multiparous women with hypertension and a history of intrauterine fetal growth retardation (in addition to those with early onset severe preeclampsia). Although a specific treatment may not be needed when autoantibodies are present, a prolonged follow-up is required since they may foretell an autoimmune disease, the clinical manifestations of which may well appear several years later.[27]

Automated analysis of near-term antepartum fetal heart rate in relation to fetal behavioral states: The Sonicaid System 8000*

Rob Mantel, MD, Herman P. van Geijn, MD, Inge A.P. Ververs, MD, and
Frans J.A. Copray, MD
Amsterdam, The Netherlands

Fetal heart rate and fetal movements were recorded in 16 uncomplicated near-term pregnancies. The recordings were used to evaluate a system for automated fetal heart rate analysis (Sonicaid System 8000). Fetal rest-activity patterns were considered in the analysis. The mean duration of C2F periods "active sleep," 33 minutes) was significantly greater than that of C1F periods ("quiet sleep," 19 minutes) ($p < 0.001$). The incidence of accelerations and decelerations and the overall fetal heart rate variations were greater during C2F than during C1F ($p < 0.001$). In 11 of 16 C1F periods, the system classified the fetal heart rate variation as "questionable" or "abnormal." Episodes of high variation were identified in only 3 of 16 C1F periods, but they were found in all 18 C2F periods. Episodes of low variation were identified in 14 of the 16 C1F periods but were not found in any C2F periods. During C2F periods, the system's criteria of normality were met in all cases but one; they were not met during any of the C1F periods. Thus the diagnosis of fetal distress should not be based merely on the absence of accelerations, low fetal heart rate variation, or absence of episodes of high variation in recordings with a duration of <45 minutes. (AM J OBSTET GYNECOL 1991;165:57-65.)

Key words: Automated analysis, antepartum fetal heart rate, fetal heart rate monitoring, fetal behavioral states, fetal rest-activity patterns, fetal movements

Antepartum fetal heart rate (FHR) monitoring is widely applied to assess the fetal condition in high-risk pregnancies. However, visual interpretation of antepartum FHR recordings is hampered by poor intraobserver and interobserver agreement.[1-3] This problem might be reduced with the help of automated FHR analysis. Such analyses would offer the obstetrician objective quantitative information on FHR parameters, including trends that occur during days to weeks.

For several years we have used a computerized system[4] to study the relationship between fetal movements, which were observed via real-time ultrasonography, and FHR. Four behavioral states have been described in the near-term fetus. These behavioral states are based on three variables: the FHR pattern, fetal body movements, and fetal eye movements.[5] The behavioral state analysis is performed semiautomatically: FHR patterns must be classified initially by visual inspection of the recordings.

Recently, a system for automated antenatal FHR analysis (Sonicaid System 8000) has become commercially available. This study evaluates how this system performs with respect to FHR recordings obtained during various fetal behavioral states.

Material and methods

Recordings. Sixteen recordings of antepartum FHR and fetal movements were obtained in uncomplicated pregnancies. Gestational age at the time of the recording (38 to 39 weeks) was confirmed by early ultrasonographic examination.

All infants were born around term and had birth weights that were appropriate for gestational age, Apgar scores of 10 at 5 minutes, and a pH of >7.20 in the umbilical artery. All infants appeared to be normal on neurologic examination.

FHR and fetal movements were recorded continuously for 2 hours. The participating women were asked not to smoke and not to drink coffee, tea, or alcoholic beverages in the 2 hours before the recording was done. The recordings took place during the afternoon. The women were in a semirecumbent position and were slightly tilted to the left. Fetal movements were observed by means of two real-time ultrasonographic units. One examiner directed the transducer to the fetal head to observe eye, mouth, and head movements. A second examiner directed the transducer to the fetal trunk so that trunk and arm movements, breathing movements, and hiccups and startles could be ob-

†Trunk, head, or arm movements.

served. Movements were recorded on line with coded event markers. Both examiners used a control device to indicate adequate visibility of the fetal orbit and trunk.[4, 6]

FHR was recorded by means of wide-range ultrasonographic equipment (HP 8040A, Hewlett Packard Co., Palo Alto). The FHR monitor supplied an analog signal that was sampled at a rate of 10 times per second and was converted from analog to digital. The sample values were stored in a computer (PDP 11/34, Digital Equipment B.V., Utrecht, The Netherlands) with the information on fetal movements.[4]

Fetal behavioral states. According to Nijhuis et al.,[5] the determination of fetal behavioral states is based on particular FHR patterns and the presence or absence of fetal eye and body movements (which consist of trunk, arm, and head movements).

The presence or absence of fetal eye and body movements was assessed via an extended automated window procedure including correction for signal loss that resulted from inadequate visibility of the fetal orbit or trunk.[4]

A Delphi group opinion procedure was applied to classify FHR patterns.[6] According to the fetal behavioral state concept, four different FHR patterns can be distinguished (Table I).[5]

Automated assessment of fetal behavioral states was performed by combining the results of the Delphi procedure (FHR patterns) and the automatic window procedure (fetal eye and body movements). Specific combinations of the parameters of body movements (absence or presence), eye movements (absence or presence), and FHR patterns (A through D) match the four fetal behavioral states (1F to 4F).[5] These combinations of state parameters, which are called coincidence 1F through coincidence 4F (C1F through C4F), are summarized in Table I. An example of a recording of FHR and fetal movements and the results of the behavioral state analysis are given in Fig. 1.

The System 8000. The System 8000 collects information on FHR, tocodynamometry, and maternal perception of fetal movements.[7-12] Data acquisition proceeds continuously up to a maximum of 60 minutes. Analysis is performed after 10 minutes and every 2 minutes thereafter. If the record appears to be normal according to the system's criteria, the computer displays *Dawes/Redman criteria met,* in which case the recording may be stopped. Otherwise, the advice *continue* is given.

In the analysis procedure the computer fits a baseline to the trace, identifies accelerations and decelerations, and calculates the FHR range in milliseconds for each minute of the trace. The computer marks episodes of high and low variation and measures basal heart rate.

Accelerations are defined as periods with an amplitude >10 beats/min above baseline and a duration >15 seconds. Criteria for decelerations are amplitude >10 beats/min below baseline and duration >1 minute or amplitude >20 beats/min below baseline and duration >30 seconds. A deceleration with an area >20 lost beats is considered large.

The overall long-term FHR variation is expressed as the mean minute range (in milliseconds), which is calculated as the average of the differences between minimum and maximum pulse intervals in each minute, unless (as during a long acceleration) all pulse intervals are less than baseline, in which case the range is measured from baseline. An overall variation >30 milliseconds is classified as normal; between 20 and 30 milliseconds, as questionable; and <20 milliseconds, as abnormal. Any minute of the trace that contains a deceleration is excluded from the calculation of the overall variation and from episodes of high variation.

An episode of high variation is a section of the trace in which at least five of every six consecutive minutes have a mean minute range that is above a certain threshold. Similarly, in an episode of low variation, five of six consecutive minutes have a mean minute range that is below a certain threshold. At the start or end of

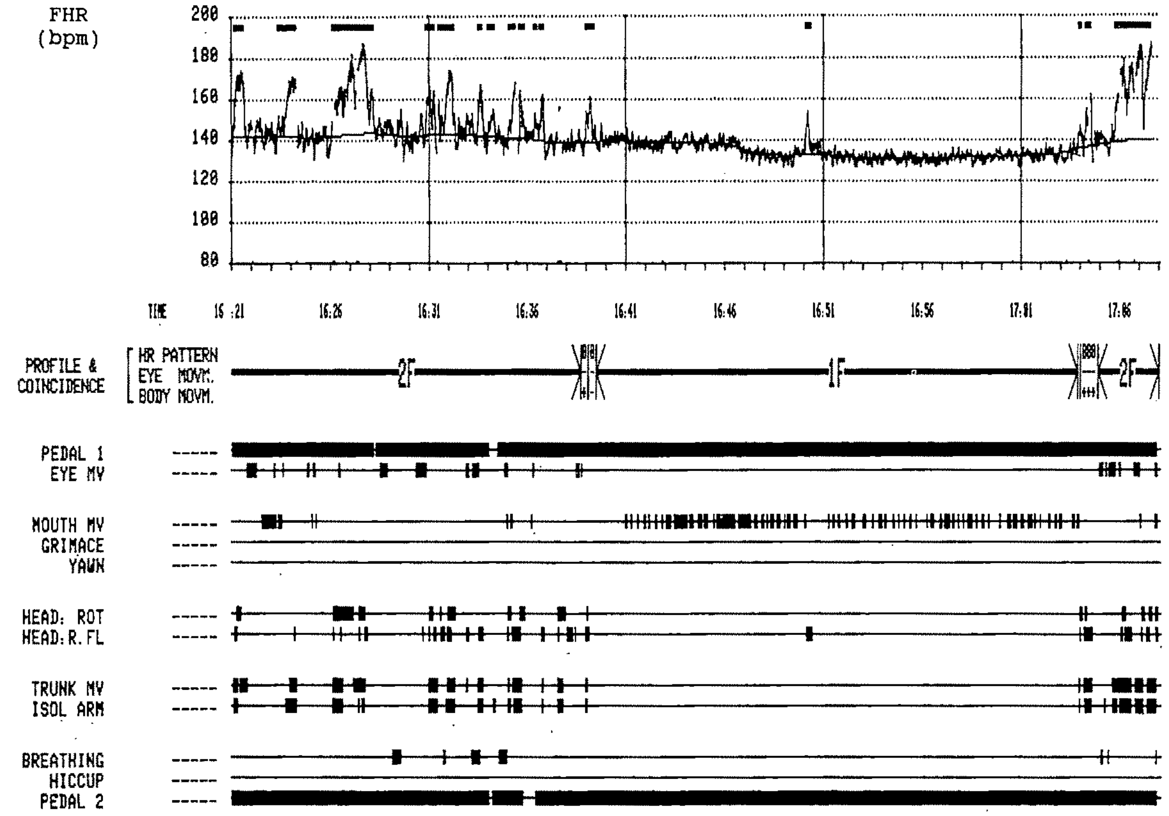

Fig. 1. Example of recording of FHR, fetal movements *(MV)*, and results of behavioral state analysis. *Top*, Automated FHR analysis according to Mantel et al.[17, 18] Accelerations are indicated by *thick solid line*. *Bottom*, Fetal movements *(MV)*. *Pedals 1 and 2* indicate adequate visibility of fetal orbit and trunk. *ROT*, Rotation; *R.FL*, retroflexion. *Middle*, Result of automated window procedure with two C2F periods (16:21:00 to 16:38:45 and 17:05:00 to 17:08:00) and one C1F period (16:39:30 to 17:03:55) between these.

a record, the computer will accept 4 of 5 minutes as an episode of high variation or an episode of low variation. On the first analysis, the thresholds are 32 milliseconds for high variation and 30 milliseconds for low variation. If the program has not found an episode of high variation after 20 minutes of FHR recording, it reduces the thresholds to 24 and 22 milliseconds, respectively, and performs a second analysis.

Basal heart rate is defined as the mean heart rate averaged during all episodes of low variation. If no episode of low variation is present, the basal heart rate is derived from a statistical analysis of the frequency distribution of pulse intervals.

The statement *Dawes/Redman criteria met* is given as soon as the following three requirements have been fulfilled: presence of an episode of high variation, identification of at least one fetal movement (from maternal perception) or of three accelerations, and absence of large decelerations.

Automated analysis of FHR in relation to fetal behavioral states. To evaluate the System 8000 in relation to fetal behavioral states, all periods C1F through C4F with a minimum duration of 10 minutes were selected from the 16 recordings. FHR signals of these periods were read from disks, were converted from digital to analog, and were sent real-time to the fetal heart rate monitor (HP 8040A, Hewlett Packard), which was connected to the System 8000. Information on uterine activity or maternal perception of fetal movements was not part of this study.

The following parameters were analyzed for each period C1F through C4F: duration (minutes), signal loss (percent), basal heart rate (beats per minute), number of accelerations and decelerations per hour, total duration of episodes of high variation and episodes of low variation (minutes and percents), overall mean heart rate variation (milliseconds), and mean heart rate variation during episodes of high variation and episodes of low variation. Finally, we evaluated whether the appropriate criteria were met and, if so, after how long and at which threshold. Statistical comparison between different periods of coincidence was performed

by analysis of variance with $p < 0.05$ used as the threshold of significance.

Results

In the 16 recordings, the following numbers of periods C1F through C4F with a duration >10 minutes were identified: C1F, 16 (12 records with one C1F period, two records with two C1F periods); C2F, 18 (14 records with one C2F period, two records with two C2F periods); C3F, 2 (two records); C4F, 4 (four records). As a result of the small numbers for C3F and C4F, further analysis was restricted to C1F and C2F. Figs. 2 and 3 show examples of the exclusive FHR analysis of C2F and C1F periods, respectively, by the System 8000.

The mean duration (19 minutes) of C1F periods (95% confidence interval, 15 to 22; range, 11 to 34) was significantly less than that of C2F periods, which was 33 minutes (95% confidence interval, 26 to 41; range, 10 to 60) ($p < 0.001$).

Mean signal loss during C1F periods was 1.2% (95% confidence interval, 0.4 to 2.0; range, 0.0 to 4.8), compared with 3.7% during C2F periods (95% confidence interval, 2.0 to 5.4; range, 0.4 to 10.0) ($p < 0.01$).

Mean basal heart rate during C1F was 136 beats/min (range, 120 to 143), compared with 137 beats/min during C2F (range, 125 to 146) ($p = 0.44$).

The mean number of accelerations per hour totaled 3.4 during C1F (95% confidence interval, 1.4 to 5.4; range, 0 to 10) and 21.5 during C2F (95% confidence interval, 17.7 to 25.4; range, 6 to 38) ($p < 0.001$).

Only 2 of 16 C1F periods contained a deceleration. In contrast, 9 of 18 C2F periods contained one or more decelerations (range, 1 to 5). This difference is statistically significant if the differences in duration of pe-

Fig. 3. Automated analysis by System 8000. Results of exclusive analysis of C1F period as shown in Fig. 1 (16:40:00 to 17:03:00). See text for explanation.

riods C1F and C2F are considered ($p < 0.001$). However, these decelerations were of small magnitude (area <20 lost beats).

During the first analysis, episodes of high variation (threshold, 32 milliseconds) were identified in only 2 of the 16 C1F periods. In both of these cases there was a shift in basal heart rate that caused a deviation from the less tractable baseline and thereby enabled identification of an episode of high variation. In all the remaining 14 cases only episodes of low variation were identified. In 7 of these 14 cases the duration of the C1F period was ≥20 minutes, in which case a second analysis was performed. This resulted in recognition of an additional episode of high variation (threshold, 24 milliseconds) in only one case. The analysis of the 14 C1F periods with episodes of low variation showed that 64% of the time during C1F (range, 25% to 100%) was spent in episodes of low variation (mean duration, 12.4 minutes; range, 5 to 30 minutes). Episodes of low variation were not found in any of the 18 C2F periods. In contrast, episodes of high variation were identified in all 18 C2F periods during the first analysis. On average, 72% of the time during C2F (range, 20% to 100%) was spent in episodes of high variation (mean duration, 23.9 minutes, range, 5 to 41 minutes).

The Dawes/Redman criteria were not met during any of the 16 C1F periods, mostly because of absence of an episode of high variation (13 cases). In the three C1F periods in which an episode of high variation was found, the criteria were not met because fewer than

Table II. Quantitative data of automated FHR analysis of C1F and C2F

The results concern 16 C1F periods (14 recordings) and 18 C2F periods (16 recordings), unless stated otherwise.

*Expressed as mean minute range, overall and exclusively during episodes of low variation *(ELV)* or high variation *(EHV)*.

†Fourteen C1F periods.

‡Three C1F periods.

three accelerations were identified. During the analyses of the 18 C2F periods, the Dawes/Redman criteria were met after 10 minutes in 12 cases, 12 minutes in 2 cases, 14 minutes in 2 cases, and 18 minutes in 1 case. The statement did not appear in one C2F period (duration, 10 minutes) because only one acceleration was identified.

The overall mean FHR variation during C1F was 25.7 milliseconds (95% confidence interval, 22 to 29; range, 14 to 36). The overall FHR variation was >30 milliseconds in 5 of 16 cases, between 20 and 30 milliseconds in 7 of 16 cases, and <20 milliseconds in the remaining four C1F periods. The lowest value (13.5 milliseconds) was found during a C1F period that lasted 22 minutes. The longest C1F period (34 minutes) had an overall mean FHR variation of 19.9 milliseconds. The overall mean FHR variation during C2F was 56.3 milliseconds (95% confidence interval, 50 to 63; range, 40 to 82), which is significantly more than during C1F ($p < 0.001$). Expressed in beats per minute instead of in milliseconds, the overall mean FHR variability was 8.6 beats/min during C1F (95% confidence interval, 7 to 9; range, 5 to 11), compared with 20.3 beats/min during C2F (95% confidence interval, 18 to 23; range, 14 to 32).

During episodes of low variation within C1F periods, which were noted in 14 of 16 cases, the mean minute range of variation varied between 13 and 27 milliseconds (average value, 18.7 milliseconds). During episodes of high variation within C1F periods, which were noted in 3 of 16 cases, this range was 32 to 46 milliseconds. In contrast, during episodes of high variation within periods C2F, which were noted in all 18 cases, the mean minute range of variation varied between 41 and 82 milliseconds (average value, 58.3 milliseconds).

The results are summarized in Table II.

Comment

In near-term recordings of 2 hours' duration, the fetus spends about 25% of the time in C1F ("quiet sleep") and about 50% in C2F ("active sleep"). The majority of remaining time is spent without coincidence of state parameters. C3F and C4F are relatively rare.[6]

The significantly shorter duration of C1F compared with that of C2F (mean values in current study, 19 vs 33 minutes) does not seem to be of great clinical importance but is discussed in greater detail at the end of this section. In reality, the difference in mean duration will even be greater because C2F periods may last for >90 minutes. In this study C2F periods could be included only up to a maximum of 60 minutes, which is the limit that the System 8000 can handle.

The significantly lower amount of signal loss during C1F (mean, 1.2%) compared with that of C2F (mean, 3.7%) corresponds to that of the literature.[8, 10] It is unlikely that this amount of signal loss could have caused the other differences found between C1F and C2F.

Lack of difference in mean basal heart rate between C1F and C2F relates to the methods in use and is difficult to interpret. Basal heart rate is defined by the System 8000 as mean rate averaged over all periods recognized as episodes of low variation. If episodes of low variation are absent, basal heart rate is derived from a statistical analysis of the frequency distribution of pulse intervals.[9] In this study no episodes of low variation were found during any of the 18 C2F periods, whereas episodes of low variation were detected in 14 of the 16 C1F periods.

The higher incidence of accelerations during C2F (mean, 21.5 per hour) compared with that of C1F (mean, 3.4 per hour) is hardly surprising because the frequency of accelerations is part of the definition of the FHR patterns (Table I). A strong association between fetal movements and accelerations in uncomplicated pregnancies is well known from the literature.[5, 7, 13-15] A similar program for automated FHR analysis (without consideration of fetal rest-activity patterns) has been used before.[10, 16] Visser et al.[16] found a mean incidence of accelerations of 14.0 per hour at 37 to 38 weeks of gestation and 15.0 per hour at 39 to 40 weeks of gestation. At 38 to 39 weeks of gestation, Dawes et al.[10] reported an overall incidence of 15.5 accelerations per hour, compared with 21.6 per hour when analyzed exclusively during episodes of high variation. It should be noted that the latter value is almost the same as that found during C2F in this study.

C2F periods more often contained decelerations than did C1F periods (50% vs 12.5%). These decelerations were small (area <20 lost beats). Most of the decelerations during C2F were either identified immediately after accelerations[7, 10, 13] or between groups of accelerations.[17, 18]

The statement *Dawes/Redman criteria met* did not appear during any of the C1F periods, but the criteria were met in 17 of 18 C2F periods. The one C2F period during which the criteria were not fulfilled contained a downward shift in basal heart rate, which caused a too-high baseline fit and resulted in the identification of only one acceleration. If perception of fetal movements had been part of this study, the criteria would probably have been met because this C2F period contained several body movements.

The strong correlation between fetal rest-activity patterns and FHR is reflected not only by the incidence of accelerations but also by the FHR variation itself. The overall mean minute range of variation during C1F (range, 14 to 36 milliseconds) does not show an overlap with that during C2F (range, 40 to 82 milliseconds). Again, this is no surprise when the definitions of the FHR patterns A and B are considered. During episodes of low variation within C1F periods, the mean minute range of variation was 18.7 milliseconds on average, compared with 58.3 milliseconds during episodes of high variation within C2F periods. These values are comparable to those found during episodes of high variation and episodes of low variation in uncomplicated near-term pregnancies when fetal rest-activity cycles were not considered.[12]

Three studies, in which a precursor of the System 8000 was used to study FHR in complicated pregnancies, will be discussed in more detail. Henson et al.[19] studied 1-hour FHR recordings of mainly growth-retarded fetuses who were delivered between 28 and 37 weeks of gestation because of antenatal fetal compromise. The overall mean minute range of variation (average value, 22.9; range, 13 to 34 milliseconds), was significantly lower when compared with that of normal pregnancies of the same gestational age.[19] The values found in the compromised group, however, are comparable to those found during C1F in this study.

A second study by the same authors indicated that growth-retarded fetuses with reduced FHR variation show rest-activity patterns similar to those of normal fetuses but that the changes in variation are of lower amplitude.[20] Within a subgroup of fetuses with the lowest variation, the mean minute range during episodes of low variation was 17.5 milliseconds, on average. In this study of uncomplicated pregnancies the mean minute range within episodes of low variation during C1F was 13 to 27 milliseconds. Both studies stress the necessity of accounting for fetal rest-activity patterns when antenatal FHR recordings are interpreted.

Smith et al.[21] studied antenatal FHR variation in relation to the respiratory and metabolic status of the compromised human fetus. The fetuses were delivered between 28 and 36 weeks of gestation because of fetal distress as judged from conventional 1-hour FHR recordings. The automated analysis of these recordings showed a significantly lower overall FHR variation when compared with the recordings of the control group. The reduced variation (average mean minute range, 20.6 milliseconds) appeared to be associated with fetal hypoxemia but not with asphyxia, which is consistent with earlier observations.[19, 22, 23] Smith et al.[21] concluded that measurement of FHR variation over 60 minutes can help to identify fetuses who are becoming hypoxemic without acidemia, that a mean minute range <20 milliseconds should be considered abnormal, and that a mean minute range between 20 and 30 milliseconds should be considered probably abnormal.

This study of uncomplicated pregnancies, however, showed that 7 of 16 C1F periods had a mean overall FHR variation between 20 and 30 milliseconds, which, according to the system's classification, should be considered questionable. In addition, there were four cases with an overall FHR variation <20 milliseconds, which should be considered abnormal. However, because these C1F periods had a duration <60 minutes, the system advised continuing the recording at the end of these periods. In this case a period of higher variation would have been entered, which almost certainly would have resulted in a mean minute range above the given threshold for abnormality. The duration of C1F periods is therefore one of the most important characteristics to consider if the results of this study are compared with those found in compromised fetuses by Henson et al.[19, 20] and by Smith et al.[21] A low FHR variation should not be considered abnormal without consideration of the duration of the recording, not even if the mean minute range is as low as 13.5 milliseconds (about 5 beats/min), which was the lowest value found during C1F in the present study.

The key question is, how long do these periods of fetal rest last in uncomplicated pregnancies? In 24-hour studies at 37 to 39 weeks of gestation, Visser et al.[24] found a mean duration of episodes of low variation of 17.1 minutes (range, 6 to 38 minutes). The percentage of time spent in low variation was subject to individual as well as diurnal variation, but there was no diurnal variation in the length of episodes of low variation.[24] Patrick et al.[25] reported the longest period of complete absence of gross fetal body movements to be 50 minutes near term (isolated movements of the extremities were not included). If fetal rest is defined as a time interval containing fewer than three consecutive accelerations, then the longest period of fetal rest was 82 minutes near term.[26] The answer to the question depends on the chosen criteria for "fetal rest." In this study the fetal behavioral state concept was used as the gold standard to determine rest-activity patterns. The longest C1F period had a duration of 34 minutes. From earlier studies, we know that C1F periods can last for 40 minutes near term, although FHR pattern A may last for 45 minutes both near term and at a gestational age of 32 weeks (unpublished data). In a recent study of uncomplicated pregnancies, basal heart rate variability was measured as bandwidth over successive 30-second intervals between accelerations. There appeared to be no significant difference in mean bandwidth during C1F at 32 weeks when compared with that at 38 weeks' gestational age (unpublished observations).

As a result of this study and results known from the literature, we concluded that the automated analysis of FHR patterns during C1F and C2F periods strongly (although indirectly) supports the association between FHR patterns and rest-activity states in utero. The criteria for normality that are used by the System 8000 are defined so that they are almost always fulfilled whenever a period of C2F with a duration of longer than 10 minutes is recorded. We furthermore conclude that a diagnosis of fetal distress should not be determined merely on the basis of absence of accelerations, a low overall mean minute range of FHR variation, or on the absence of periods of high variation if the recording did not last >45 minutes. Obstetricians should be aware that analysis of FHR recordings of compromised fetuses may give results that are comparable to those found in uncomplicated pregnancies during C1F. The advice of the system, which is to continue recording until the criteria are met (if necessary, for as long as 60 minutes), may prevent errors in the interpretation of antepartum FHR recordings.

We thank Mrs. E.E. van Woerden, MD, for placing the recordings of FHR and fetal movements at our disposal. We are grateful to H.C. Schoemaker, MSc, for his valuable advice concerning the statistical analysis of this study.

A life-threatening sexually transmitted *Haemophilus influenzae* in septic abortion: A case report

**Orit Pinhas-Hamiel, MD,[a] Eyal Schiff, MD,[b] Gilad Ben-Baruch, MD,[b]
Shlomo Mashiach, MD,[b] and Brian Reichman, MB, ChB[a]**
Tel-Hashomer, Israel

Haemophilus influenzae infections of the genitourinary tract are rare. A case of a life-threatening *Haemophilus influenzae* bacteremia associated with a septic abortion is presented. Sexual transmission of bacteria after orogenital contact is proposed as a possible source of this uncommon infection. (AM J OBSTET GYNECOL 1991;165:66.)

Key words: *Haemophilus influenzae*, septic abortion

Haemophilus influenzae infections are uncommon in adults, usually manifested as pneumonia or bronchitis. Although genitourinary tract *H. influenzae* infections are rare, tuboovarian abscess, salpingitis, and urinary tract infections have been reported. *H. influenzae* in septic abortion was first described in 1973.[1] Since then only a few cases have been reported, generally characterized by mild maternal course (i.e., a virtual absence of symptoms or low-grade fever). Most of these women did not need treatment. Recently, however, we treated a patient with hypotension, shock, and disseminated intravascular coagulation as a result of *H. influenzae* infection associated with septic abortion.

Case report

A 28-year-old gravida 3, para 1 woman whose pregnancy had been uneventful up to 13 weeks' gestation was admitted to our department because of vaginal bleeding and high fever (up to 40° C) of 36 hours' duration. Results of a physical examination were normal and vaginal inspection revealed a dilated cervical os and amniotic fluid leakage. Broad-spectrum antibiotic therapy was administered and uterine curettage was performed after induction of general anesthesia. A few hours later high fever, chills, hypotension, oliguria, and confusion developed in the patient. Laboratory findings revealed leukopenia (1800/mm^3), anemia (9.3 gm/dl), thrombocytopenia (60,000/mm^3), prolonged partial thromboplastin time (60 seconds), abnormal prothrombin time (25%), elevated fibrinogen split-products level (400 mg/dl), elevated levels of liver enzymes (serum glutamate oxaloacetate transaminase 215 U/L, serum glutamate pyruvate transaminase 163 U/L), bilirubin (4.6 mg/dl), and compensated metabolic acidosis. Chest roentgenogram was normal. The patient was admitted to the intensive care unit and required therapy with intravenous dopamine and blood-product transfusions. Nontypable *H. influenzae* was isolated in blood cultures and antibiotic treatment was administered according to bacterial sensitivity.

Comment

H. influenzae is only rarely a vaginal commensal organism, accounting for <1% of bacterial growth. Recently, an increasing incidence of *H. influenzae* neonatal sepsis has been reported.[2] Sexually transmitted *H. influenzae* after orogenital contact has been proposed as a possible source of urogenital infection.[1] Our patient reported orogenital sexual contact approximately 72 hours before the onset of symptoms. Thus it seems that the incidence of *H. influenzae* urogenital infection may be affected by changes in sexual behavior, as has been noted in infections with other throat microorganisms. In contrast with the mild clinical disease in previously reported cases of *H. influenzae*–infected abortions or *H. influenzae* peripartum infections, this case warns that *H. influenzae* infection associated with septic abortion may run a severe, life-threatening course.

The association between human papillomavirus deoxyribonucleic acid status and the results of cytologic rescreening tests in young, sexually active women

Anna-Barbara Moscicki, MD,[a] Joel M. Palefsky, MD,[b] John Gonzales, MD,[c] and Gary K. Schoolnik, MD[d]
San Francisco and Stanford, California

We examined the utility of cytologic rescreening tests in women who had positive test results for human papillomavirus deoxyribonucleic acid but who were diagnosed as having benign conditions at cytologic testing. One hundred twenty-five Papanicolaou smears from women who were screened for human papillomavirus deoxyribonucleic acid were sent routinely to a private laboratory for diagnoses. These slides were then reviewed independently by two pathologists who were blinded to the human papillomavirus deoxyribonucleic acid results. The effects of cytologic rescreening in cases of both positive and negative human papillomavirus deoxyribonucleic acid were assessed by calculating *z* scores. Cervical intraepithelial neoplasia was diagnosed in 40% by pathologist A and in 20% by pathologist B of the human papillomavirus–positive subjects compared with none diagnosed by the private cytology laboratory ($z = 3.09$, $p < 0.005$ and $z = 1.98$, $p < 0.05$, respectively). No significant differences were found in the human papillomavirus–negative group. We conclude that cytologic rescreening in human papillomavirus deoxyribonucleic acid–positive women who were initially diagnosed as having benign cytologic results will yield a significant proportion of cases of cervical intraepithelial neoplasia. (AM J OBSTET GYNECOL 1991;165:67-71.)

Key words: Human papillomavirus, cytology, rescreening

The strong association between cervical neoplasia and human papillomavirus (HPV) infection[1, 2] has stimulated interest in HPV diagnostic tests. Currently, the Papanicolaou smear is used as the primary screening test for cervical disease, including condyloma and intraepithelial neoplasia.[3] However, the Papanicolaou smear appears to be relatively insensitive, detecting only 50% to 80% of the abnormalities found by histologic examination of cervical biopsy specimens obtained by colposcopy.[4-6] Routine colposcopy remains a time-consuming and cost-ineffective means to identify cervical disease. Therefore tests that identify HPV deoxyribonucleic acid (DNA) have been developed in the hope that these techniques may augment our ability to precisely identify women who are infected with HPV and who may be at risk for cervical intraepithelial neoplasia.[7] The indications for and clinical utility of these DNA detection tests have not yet been established. However, the correlation between HPV DNA status and cytologic abnormalities is not absolute[6]; i.e., some women with abnormal Papanicolaou smears will not have detectable HPV DNA and, conversely, many patients with detectable HPV DNA appear to have normal Papanicolaou smears. Therefore, whereas HPV detection tests could augment cytologic testing, they are not equivalent replacements.

It has been suggested that HPV DNA testing may be used to identify women at high risk for cervical intraepithelial neoplasia. Previous studies have reported that when cytologic smears from women who are HPV positive and who have "normal" cytologic results are reviewed additional cytologic abnormalities (including intraepithelial neoplasia) can be detected.[8, 9] These findings seem to indicate that the combined use of HPV DNA testing and the Papanicolaou smear might improve the identification of women with cervical disease. Unfortunately, the results of these studies are difficult to interpret because the smears were reviewed by pathologists who knew the HPV DNA status of the spec-

Sexually transmitted disease related	10%

imens at the time the reviews were conducted, possibly biasing the outcome. We describe a study that examines the association between HPV DNA status and diagnostic interpretations on review of cytologic results by two independent pathologists who were without knowledge of the HPV DNA results.

Methods

This study was part of a large epidemiologic study examining the prevalence of HPV DNA in sexually active adolescents.[10] All female adolescents (aged 13 to 19 years) who were attending a private, suburban family planning clinic and having a pelvic examination for any reason were asked to enter this study according to the guidelines set by the Committee for Human Research to screen for the presence of cervical HPV DNA. The refusal rate was <10%. Populations attending the clinic were predominantly middle-class and the racial-ethnic distribution of the clinic was 60% white, 20% black, 20% Hispanic, and 10% other. All female adolescents who entered the study were asked to complete a self-administered questionnaire before examination; this included demographic and sexual behavior information. Pelvic examination included a Papanicolaou smear obtained with a Dacron swab and spatula followed by an endocervical and exocervical sample for HPV DNA with a Dacron swab. Slides for cytologic testing were immediately fixed in alcohol and were sent to a contracted private cytology laboratory for initial review per routine protocol. Slides from 134 consecutive subjects during the second month through the fourth month of the study were identified and released for review by two independent pathologists. Although the two pathologists were without knowledge of the HPV DNA status of each specimen and were not apprised of the specific purpose of the review, they were asked to carefully review the slides for the epidemiology study.

Cytology. Papanicolaou smears were prepared by standard methods at the private cytology laboratory and were then screened according to the following routine protocol. All smears were first screened by a cytotechnician. Those smears found to have abnormal findings including inflammation, atypia, and changes suggestive of condyloma and neoplasia, as well as 10% of the benign smears, were then reviewed by a supervising pathologist. Cytologic diagnoses from the private laboratory were categorized into one of the following: benign, atypia, or cervical intraepithelial neoplasia with or without koilocytosis. The term *cervical intraepithelial neoplasia* is used for easier reference in this article although it is understood that cytologic testing cannot determine the site of origin of neoplastic cells.

Pathologist A then reviewed each slide independently without knowledge of either the HPV DNA status or the private laboratory's cytologic diagnosis at × 10 magnification with higher magnification used for the examination of questionable or abnormal areas. For comparison, the second pathologist (pathologist B) used a method more common to cytology laboratories; that is, a cytotechnician screened the smears first and then pathologist B verified the diagnosis of all the smears. The diagnoses reported by the reviewing pathologists were categorized as described here. Standard criteria were used to diagnose neoplasia and koilocytosis.[11] Atypia was diagnosed when rare abnormal cells (neoplastic or koilocytes) were found or if some but not all of the features of cervical intraepithelial neoplasia or koilocytosis were found on Papanicolaou smears. Since cytologic correlates for condyloma are controversial, cells suggestive of condyloma (koilocytes) but without the nuclear features of neoplasia also were categorized as atypia. Slides that appeared to have been air-dried or inadequately stained were excluded from the analysis. The presence or absence of endocervical cells was noted by the reviewing pathologists.

HPV DNA hybridization. HPV DNA was identified with a commercially available ribonucleic acid–DNA dot blot hybridization technique (ViraPap).[12] Cervical swabs for HPV were immediately placed into 1 ml of the sample transport medium and refrigerated at 4° C for no longer than 2 weeks before processing. Samples were processed with the ViraPap method according to the manufacturer's recommendation.[12] This method allows for identification of HPV types 6, 11, 16, 18, 31, 33, and 35. Unused portions of the samples that were positive for the HPV probe mixture were then studied under similar conditions to determine the HPV type more precisely. Samples were filtered onto three separate membranes, and each membrane was then hybridized with one of three separate radioactively labeled probe mixtures: type 6/11, type 16/18, or type 31/33/35.[13]

Table II. Comparison of cytologic diagnoses among pathologists A and B and the private cytologic laboratory for HPV-positive and HPV-negative subjects

	Privatate cytologic laboratory: HPV positive			*Privatate cytologic laboratory: HPV negative*		
	Benign	*Atypical*	*Cervical intraepithelial neoplasia*	*Benign*	*Atypical*	*Cervical intraepithelial neoplasia*
Pathologist A						
Benign	9	0	0	92	1	0
Atypia	5	1	0	6	0	0
Cervical intraepithelial neoplasia	4	5	0	0	2	0
Pathologist B						
Benign	13	0	0	93	1	0
Atypia	3	3	0	4	1	0
Cervical intraepithelial neoplasia	2	3	0	1	1	0

Data analysis. For each of the reviewers, χ^2 tests were performed to examine the relationship between HPV DNA status and diagnosis. Interrater reliability is reported for agreement between the two reviewing pathologists. The effect of rescreening was assessed by calculating *z* scores. This test examined whether rescreening of HPV-positive subjects and HPV-negative subjects resulted in a significant difference in the proportion of subjects with a diagnosis of cervical intraepithelial neoplasia by the private cytology laboratory (first screen), when compared with diagnoses assigned by pathologist A or B (rescreens). Because the private cytology laboratory did not diagnose any cases of cervical intraepithelial neoplasia, a second variable for cytologic diagnosis was created for comparison. This variable compared only two categories: benign and any abnormality (atypia or cervical intraepithelial neoplasia). The *z* test was also performed to examine the difference in the proportion of subjects with any abnormality.

Results

Population characteristics. Table I describes the demographic characteristics of the subjects including sexual behaviors and reasons for visit. Twenty-four subjects (19%) had positive HPV DNA results: 5 were positive for group 6/11, 11 for group 16/18, 4 for group 31/33/35, and 1 for both group 16/18 and group 31/33/35. Three subjects had undetermined types with the described dot blot method.

Interrater reliability between the pathologists. The overall interrater reliability between the two pathologists with three cytologic categories (benign, atypia, and cervical intraepithelial neoplasia with or without koilocytosis) was 79% ($\kappa = 0.28$, $p = 0.001$). When categories were subdivided into *benign* and *any cytologic abnormality,* the interrater reliability was 86% ($\kappa = 0.51$, $p = 0.001$). For the latter analysis, the interrater reliability was 75% ($\kappa = 0.51$, $p < 0.002$) in the HPV-positive group and 89% ($\kappa = 0.208$, $p < 0.03$) in the HPV-negative group.

Comparison of cytologic diagnosis and HPV DNA status. There was a significant association between abnormal cytologic findings and positive HPV DNA status for the private cytology laboratory, pathologist A, and pathologist B. The private cytology laboratory found that none of the patients had cervical intraepithelial neoplasia; however, 6 of 24 HPV-positive subjects had atypia, compared with 3 of 101 HPV-negative subjects ($\chi^2 = 10.98$, $p < 0.0009$). Pathologist A diagnosed abnormal cytologic findings in 15 of 24 women in the HPV-positive group (9 with cervical intraepithelial neoplasia and 6 with atypia) compared with 8 of 101 women in the HPV-negative group (2 with cervical intraepithelial neoplasia and 6 with atypia) ($\chi^2 = 42.2$, $p < 0.0001$). A similar association was found for pathologist B; 11 of 24 HPV-positive women had abnormal cytologic findings (5 with cervical intraepithelial neoplasia and 6 with atypia) and 7 of 101 HPV-negative women had abnormal cytologic findings (2 with cervical intraepithelial neoplasia and 5 with atypia) ($\chi^2 = 24.59$, $p < 0.0001$).

Comparison of cytologic findings among the private laboratory and pathologists A and B within HPV-positive and HPV-negative groups. Table II compares the cytologic diagnoses of the private cytology laboratory with those of pathologist A and pathologist B by HPV DNA status. Of the cervical intraepithelial neoplasia cases diagnosed, only 2 had grade 2; the rest had grade 1. Both cases of grade 2 were assigned the same diagnosis by both pathologist A and pathologist B; both of these women were HPV positive. Pathologist A diagnosed 38% of the HPV-positive patients as having cervical intraepithelial neoplasia, compared with none diagnosed by the private cytology laboratory ($z = 3.09$, $p < 0.005$); pathologist A diagnosed *any cytologic abnormality* in 63% of the HPV-positive patients, compared with 25% by the private cytology laboratory ($z = 2.39$, $p < 0.03$). In contrast, there was no significant difference in the proportion of abnormal cytologic smears diagnosed in the HPV-negative group. Specifically, 2% of HPV-negative subjects were diagnosed to have cervical intraepithelial neoplasia by pathologist A and none were diagnosed by the private cytology laboratory ($z = 0.714$, difference not significant). Similarly, no difference was found for diagnosing "any cytologic abnormality" in the HPV-negative group ($z = 0.15$; difference not significant). In addition, 5 of the 6 subjects who were HPV positive and were diagnosed as having atypia by the private cytology laboratory had cervical intraepithelial neoplasia. Two of the subjects with atypia and who were HPV negative had cervical intraepithelial neoplasia.

Pathologist B also found significantly more subjects with cervical intraepithelial neoplasia on rescreening the HPV-positive group than were diagnosed by the private cytology laboratory, 21% by pathologist B versus 0% by the private cytology laboratory ($z = 1.98$, $p < 0.05$). However, there was no difference between the private cytology laboratory and pathologist B in the proportion of subjects with a diagnosis of cervical intraepithelial neoplasia among the HPV-negative group ($z = 0.714$, difference not significant). Pathologist B diagnosed *any cytologic abnormality* in 46% of HPV-positive subjects, compared with 25% diagnosed by the private cytology laboratory ($z = 1.2$; difference not significant). There was also no significant difference found between the proportion of those subjects with a diagnosis of *any cytologic abnormality* between pathologist B and the private cytology laboratory among the HPV-negative group ($z = 0.15$, difference not significant).

When readings between the two groups were compared by each HPV category, the significant differences found between the two readings remained similar for each HPV group (data not shown). In addition, the presence or absence of endocervical cells did not influence the differences in diagnosis on reviews.

Comment

This study demonstrates that a significant proportion of HPV-positive women in our study were diagnosed as having cervical intraepithelial neoplasia when their Papanicolaou smears were rescreened. In contrast, cytologic rescreening from HPV-negative women did not result in a significant proportion of additional abnormal diagnoses. This association was less clear for diagnosing the category *any cytologic abnormality* because pathologist A was more likely than the private cytology laboratory to identify atypia on smears from HPV DNA–positive women, whereas no such association was found for pathologist B. However, the clinical implications for atypia are controversial and this cytologic category is considered less predictive of a significant lesion.

Our findings suggest that the reported insensitivity of the Papanicolaou smear is due in part to screening error. Currently, the Papanicolaou smear is the primary screening tool to identify women with cervical disease, specifically intraepithelial neoplasia. Although this kind of cytologic screening remains the most cost-effective method, numerous studies have identified the limitations of the Papanicolaou smear, including substantially lower sensitivity rates than those of colposcopy and histology.[4-6] These limitations have been attributed to sampling error, difficulty in cytologic interpretation, and fatigue (in both cytotechnicians and pathologists) resulting in screening error.[14, 15] Although most laboratories set high standards for quality assurance, previous studies have documented that reviews of cytologic smears will result in a fivefold increase in the number of significant abnormalities as compared with the results from the initial routine screening.[16] Our study both confirms and extends these findings. We showed that additional abnormalities were found when cytologic smears were reviewed. However, when the rescreening results were analyzed by HPV status, the majority of additional significant abnormalities were present in the HPV DNA–positive group even though the reviewers were blinded to the HPV DNA status. This finding suggests that it would be more efficacious to review smears from this positive population.

Although our findings apppear to have important implications for the cytologic identification of cervical intraepithelial neoplasia, these results must be interpreted with caution. First, the clinical significance of the reviews is unknown because we did not perform colposcopic examinations and obtain histologic confirmations. It is possible that some of our reviews reflect erroneous diagnoses; however, this is unlikely since the positive predictive value of the Papanicolaou smear to identify disease is considered to be relatively high.[6] Our pathologists used strict criteria to diagnose disease. In addition, statistical analysis of our data indicated that the association between HPV DNA status and abnormal reviews was greater than chance alone.

Second, our findings may not necessarily be generalizable because the quality of screening can vary considerably among laboratories.[16] As a result, it is possible that our findings simply reflected a higher-quality screening process. However, we feel that our results were not biased by this possibility for several reasons. First, it should be stressed that, although the reviewers were without knowledge of the HPV status, they were aware that they were reviewing slides for a study that possibly reflected an increased "effort per slide" and were reviewing slides without the conventional pressures associated with rapid bulk screening. This situation may reflect a similar situation found when slides are reviewed for routine quality assurance measures. In addition, if the reviewers were significantly "better" at screening, it would have been more likely that additional abnormalities would have been found proportionately in both groups. Finally, the percent agreement between the pathologists reflected "differences in opinion" similar to those found in other studies.[17] To help remove the "type-of-reader" bias, we selected two types of review: One involved an independent pathologist and the other involved a screening cyto-technician-pathologist team. The two groups occasionally disagreed; however, both were significantly more likely to find additional abnormalities in the HPV-positive group and not in the HPV-negative group.

Another factor that influences the generalizability of our findings is the population examined. Our population consisted of sexually active young women with a high prevalence of HPV and cervical intraepithelial neoplasia (14% had cervical intraepithelial neoplasia on the reviewed smears). The prevalence of these factors may affect the outcome in such studies.

Last, our abnormal smears with cervical intraepithelial neoplasia were associated with a high rate of DNA positivity (86%). This rate is higher than that reported in other studies,[18, 19] which may reflect the high prevalence of these specific HPV types in our population and the association between these types and abnormal cytologic findings.

In summary, reviewing cytologic results in patients who are HPV DNA positive increased the number of diagnosed cases of cervical intraepithelial neoplasia. This suggests that in a population at high risk for HPV and cervical intraepithelial neoplasia but with normal cytologic findings, routine screening for HPV DNA would be beneficial if the cytologic findings from HPV DNA–positive women are reviewed. Longitudinal studies that include colposcopy and histology are currently under way to confirm these findings.

We thank Dr. Barbara Winkler for her assistance in the reviews of the Papanicolaou smears. We also thank Roy Rodriguez for his assistance in manuscript and figure preparation.

The effect of trisomy 18 on transverse cerebellar diameter

Lyndon M. Hill, MD,[a] Sandra Marchese, MS,[b] Carol Peterson, RDMS,[a] and Joanne Fries, RDMS[a]
Pittsburgh, Pennsylvania

The transverse cerebellar diameter was measured in 19 fetuses with trisomy 18. Eleven of the cerebellar measurements (57.9%) were >2 SD below the mean for the patient's gestational age. If fetal biometry rather than last menstrual period were used to determine gestational age, four of the 19 (21.0%) cerebellar measurements were >2 SD below the mean. Both intrauterine growth retardation and intrinsic central nervous system abnormalities associated with trisomy 18 appeared to affect cerebellar size. (Am J Obstet Gynecol 1991;165:72-5.)

Key words: Transverse cerebellar diameter, trisomy 18

The ultrasonographic findings associated with trisomy 18 have been well documented.[1, 2] The clinical features of this syndrome are numerous and vary from case to case.[3] Although malformations of the central nervous system are relatively uncommon, cerebellar abnormalities have occasionally been reported.[4] Inagaki et al.,[5] for example, found a small cerebellum (and hydrocephalus) in five newborns with trisomy 18. To date there have been only a few reports on the antenatal evaluation of the cerebellum and cisterna magna in fetuses with trisomy 18. Comstock and Boal[6] reported two cases and Thurmond et al.[7] five cases of third trimester trisomy 18 fetuses with a small cerebellum and an enlarged cisterna magna. The purpose of our investigation was to determine if the transverse cerebellar diameter was consistently smaller than expected in a larger series of second-trimester, as well as third-trimester, trisomy 18 fetuses.

Material and methods

We retrospectively ascertained all consecutive karyotypic diagnoses of trisomy 18 made at Magee-Womens Hospital from May 1986 to May 1990 and identified those women who had an ultrasonographic examination. Exclusion criteria included insufficient dating parameters (see below) or intrauterine fetal death at the time of the ultrasonographic examination.

For entry in the study these criteria for ascertaining dates were required: regular menses, no oral contraceptives for 3 months before conception, an early pregnancy test, and a first pelvic examination at or before 10 weeks' gestation.

Twenty-one fetuses with a karyotypic diagnosis of trisomy 18 met these entrance criteria. In two cases an Arnold-Chiari type II malformation prohibited visualization of the cerebellum. The latter cases were excluded from further analysis; hence there were 19 fetuses in the study group.

A thorough ultrasonographic examination was performed with a linear array real-time system with a 3.5 or 5.0 MHz transducer (General Electric RT3000, RT3200, General Electric Corp., Milwaukee). A composite assessment of gestational age was obtained from standard biometric measurements of biparietal diameter, femur length, head circumference, and abdominal circumference. The amount of amniotic fluid and the placental site were documented.

We have consistently measured the transverse cerebellar diameter as part of our routine anatomic survey since 1986. A slightly posterior angulation from the plane of the biparietal diameter allows visualization of the cerebellum (Fig. 1). The normal cerebellar diameter for our population as a function of gestational age was derived prospectively from 675 patients with normal pregnancy between 14 and 42 weeks' gestation according to above-noted dating criteria.[8] A transverse cerebellar diameter ≥2 SD below the mean for gestational age was defined as abnormal (Fig. 2).

Results

The transverse cerebellar diameters in the 19 fetuses with trisomy 18 are plotted on Fig. 3 versus gestational age by a reliable last menstrual period. Eleven of the cerebellar measurements (57.9%) were ≥2 SD below the mean. When the transverse cerebellar diameter was compared to the patient's gestational age by fetal biometry rather than by last menstrual period, only four of

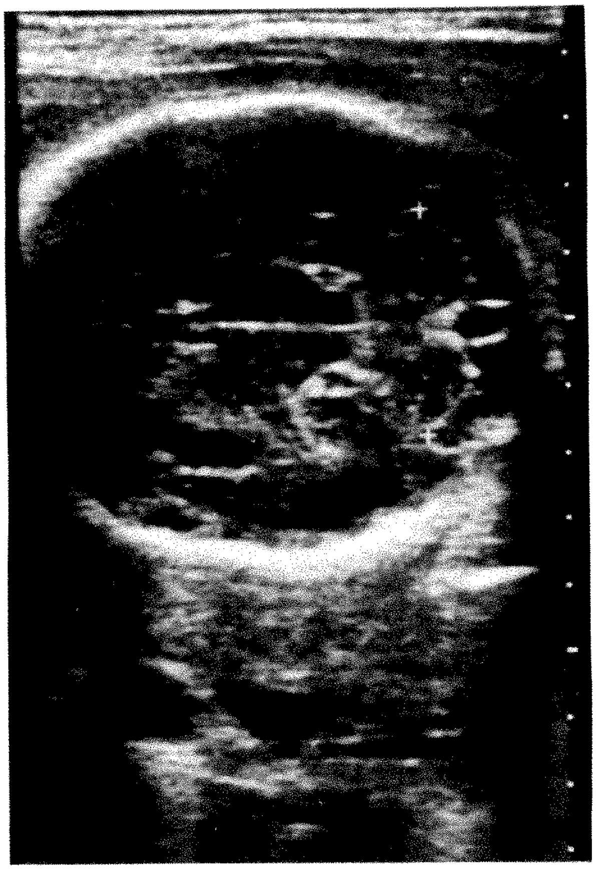

Fig. 1. *Graticules* demarcate transverse cerebellar diameter in chromosomally normal fetus at 29 weeks' gestation.

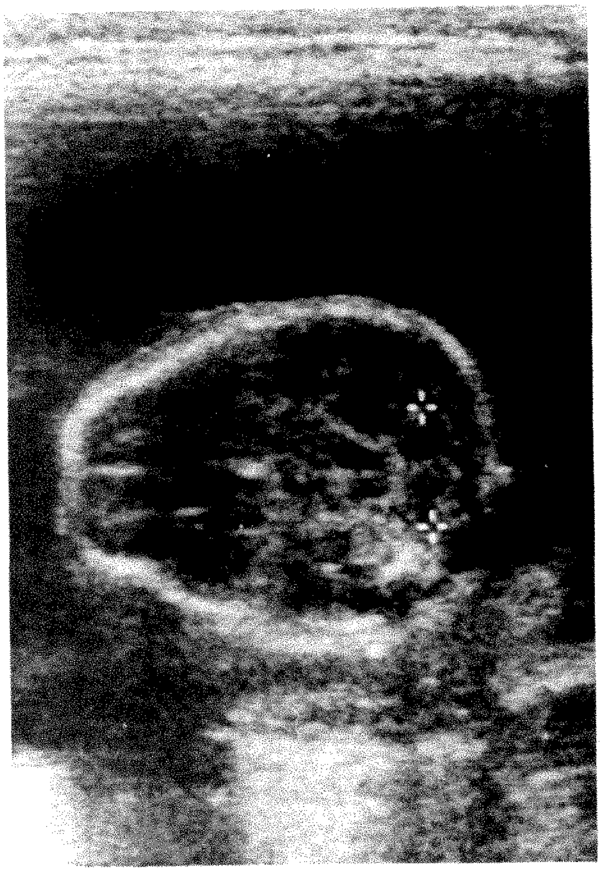

Fig. 2. Trisomy 18 fetus with cerebellar hypoplasia at 31 weeks' gestation. *Graticules* demarcate transverse cerebellar diameter of 22 mm.

19 measurements (21%) were >2 SD below the mean. Consequently, if a patient's dates are uncertain, the transverse cerebellar diameter, as well as standard biometry, may give rise to an incorrect estimation of gestational age.

The likelihood that the transverse cerebellar diameter would be small appears to increase with gestational age—two of seven fetuses (28.6%) before 21 weeks' gestation versus nine of 12 (75%) third-trimester fetuses had a cerebellar diameter >2 SD below the mean.

In contrast to the findings of Comstock and Boal[6] and Thurmond et al.,[7] the cisterna magna was enlarged (≥1.1 cm)[9] in only three of the 12 fetuses evaluated in the third trimester.

Four of the 19 fetuses had normal fetal biometry at the time of their ultrasonographic examination (17, 17, 19.4, and 30.8 weeks, respectively); two of the fetuses in this group had a normal transverse cerebellar diameter, and two had cerebellar hypoplasia. Of the 15 growth-retarded trisomy 18 fetuses, six had a normal transverse cerebellar diameter and nine had a transverse cerebellar diameter >2 SD below the mean. Hence there appears to be two potential mechanisms for the presence of cerebellar hypoplasia in fetuses with trisomy 18: an inherent abnormality in brain growth or a generalized inhibition of fetal growth.

Comment

Edwards' syndrome (trisomy 18)[8] was first described in 1960. The frequency of trisomy 18 is between 1 in 3500 and 1 in 8000 births.[10] However, these figures do not take into account the spontaneous in utero attrition rate. Between 16 weeks' gestation and term 68% of trisomy 18 fetuses either will abort or will be stillborn.[11] The ultrasonographer may therefore encounter fetuses with trisomy 18 more than twice as frequently as the birth statistics indicate.

The neuropathologic changes associated with trisomy 18 tend to be quite variable and hence are not diagnostic. Hydrocephalus with or without meningomyelocele, agenesis of the corpus callosum, and a small cerebellum are among the central nervous system malformations that are potentially detectable with antenatal ultrasonography.[12] Even when the cerebellum appears to be normally formed, a microscopic examination may reveal numerous structural alterations.

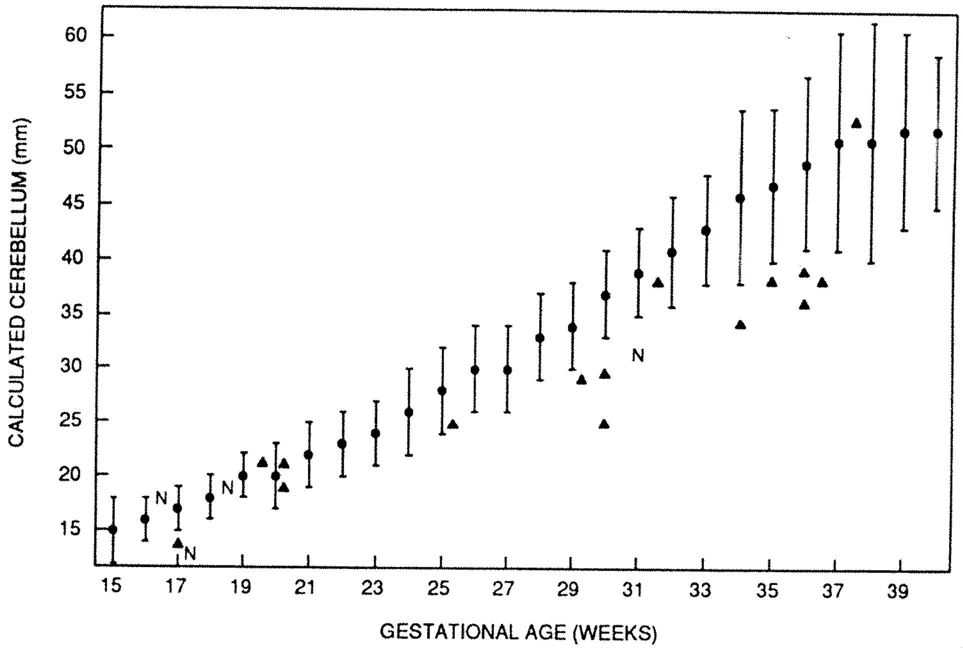

Fig. 3. Calculated mean (± 2 SD) for transverse cerebellar diameter versus gestational age in weeks. Trisomy 18 fetuses: *N*, Adequate growth; ▲, growth retardation.

The association between chromosomal abnormalities and intrauterine growth retardation is well known.[13] The severity of growth delay with trisomy 18 appears to be variable in time of onset and in severity. Although birth weights for fetuses with trisomy 18 are generally reduced, the range is quite wide.[14]

Growth of the fetal cerebellum begins later, finishes sooner, and occurs faster than does the growth of other parts of the brain. The vulnerability of the brain during its growth spurt has been well documented.[15] In a previous study[16] of 44 chromosomally normal, small-for-gestational-age fetuses, the transverse cerebellar diameter was >2 SDs below the mean in 26 (59.1%). There was a wide variation in transverse cerebellar diameter measurements at each weight percentile, emphasizing the importance of the severity, duration, and type of growth inhibition. Our current results indicate that cerebellar size in fetuses with trisomy 18 may be affected not only by an inherent inhibition of brain growth but also by the generalized disturbance of overall size associated with this specific chromosomal abnormality.[17] However, the presence of significant growth retardation did not result in cerebellar hypoplasia in every case; two fetuses in the third trimester (31.7 and 38 weeks' gestation) and three second-trimester fetuses affected by early growth retardation (20, 20, and 23 weeks' gestation) had a normal transverse cerebellar diameter.

Although other authors[6, 7] have reported an association between trisomy 18 and an enlarged cisterna magna, nine of 12 third-trimester fetuses in the current investigation had a normal cisterna magna. Nakamura et al.[18] have reported hypoplasia of the bony posterior cranial fossa in three of nine trisomy 18 neonates, resulting in a small cisterna magna or its absence. Hence the difference in results between the current and previous[6, 7] studies may be due to: (1) structural differences within the posterior fossa between trisomy 18 fetuses, (2) the severity of growth retardation, or (3) sample size.

Our findings with respect to the transverse cerebellar diameter and cisterna magna once again confirm the wide scatter about the mean for almost any biometric measure that has been obtained in trisomy 18 fetuses.[19]

The ultrasonographic findings associated with trisomy 18 vary considerably. Benacerraf et al.[2] were able to detect 12 of 15 (80%) trisomy 18 fetuses by using the ultrasonographic criteria of abnormalities of the face and limbs or a diaphragmatic hernia. The ultrasonographic detection of cerebellar hypoplasia should alert the ultrasonographer to the possibility of trisomy 18. However, measurement of the transverse cerebellar diameter or evaluation of the cisterna magna cannot replace a thorough anatomic survey in the detection of this particular chormosomal abnormality.

Porencephalic cyst: A complication of fetal intravascular transfusion

Gary A. Dildy III, MD, Leon G. Smith, Jr., MD, Kenneth J. Moise, Jr., MD,
Lorraine E. Cano, RN, and Diane E. Hesketh, RN
Houston, Texas

A case of unilateral porencephalic cyst as a result of intravascular intrauterine transfusion is reported. Although other factors may have contributed, fetal bradycardia and relative hyperviscosity as a result of increased fetal hematocrit value were considered to be related to this event. Because some authors recommend direct intravascular transfusion to supraphysiologic hematocrits to prolong the interval between procedures, we would caution the use of this approach on the basis of theoretic considerations and the occurrence of this complication. (AM J OBSTET GYNECOL 1991;165:76-8.)

Key words: Porencephalic cyst, intravascular transfusion, intrauterine transfusion, Rh alloimmunization

Direct fetal intravascular transfusion has become an important method of treating the anemic fetus. Reported complications of intravascular transfusion include umbilical cord hematoma and fetal bradycardia. We report a patient treated for Rh alloimmunization whose fetus developed a left cerebral porencephalic cyst after intravascular transfusion complicated by fetal bradycardia and an elevated fetal hematocrit value.

Case report

A 28-year-old gravida 2, para 1 woman presented at 12 weeks' gestation for prenatal care with an anti-D titer of 64. In her only previous pregnancy she was delivered by cesarean section at term because of fetal distress of a 3992 gm male infant whose blood type was reportedly Rh negative. The patient gave an otherwise negative medical history with the exception of having received a blood transfusion at age 16 years for undetermined reasons. Her husband's blood type was A positive, heterozygous for the D antigen.

At 21.4 weeks' gestation, the indirect Coombs titer rose to 512 and fetal blood sampling was performed through an anterior fundal placenta after documentation of normal results of an ultrasonographic examination. The fetal hematocrit was 34.9% and the fetal blood type was O positive. An indirect Coombs titer of 8192 obtained at 24.1 weeks' gestation to exclude an amnestic maternal antibody response necessitated repeat fetal blood sampling. The hematocrit value was 28.8%.

Five days later, fetal ascites and a small pericardial effusion were noted on ultrasonographic examination at the time of preparation for intrauterine transfusion. Pretransfusion fetal hematocrit value was 17%. Forty milliliters of filtered maternal packed red blood cells (hematocrit, 84%) were transfused intravascularly into the fetus. Blood was filtered twice, once through a leukocyte-poor filter during blood bank processing and again with a standard blood transfusion filter at the time of transfusion. The interval fetal hematocrit value was 55%. Umbilical venous pressure was noted to rise from 10 mm Hg at the onset of the procedure to 23 mm Hg after completion of the transfusion. Nine milliliters of fetal blood was slowly removed to reduce umbilical venous pressure and avoid hyperviscosity. At the completion of the procedure, a fetal bradycardia to 60 beats/min was noted, resolving spontaneously after 7 to 10 minutes.

Ultrasonographic examination at 26.1 weeks' gestation, before the second intrauterine transfusion, demonstrated a new finding of left cerebral ventricular enlargement (Fig. 1). Transfusions were repeated at 26.1, 28.1, 31.1, and 33.9 weeks' gestation without difficulty. There was no progression of the cystic cerebral lesion on serial ultrasonography. A 2200 gm female infant with Apgar scores of 7 at 1 minute and 9 at 5 minutes was delivered by repeat cesarean section at 35.9 weeks' gestation. Phototherapy was required for 3 days. Computed tomography scan without contrast on the day 9 after birth demonstrated atrophic changes of the left cerebral hemisphere with atrophic enlargement of the left lateral ventricle (Fig. 2). The infant was discharged home on the day 10 after birth; neurologic status was noted to be normal.

Comment

To our knowledge, congenital malformations as a result of intrauterine transfusion have not been previously described. The potential exists for vascular accidents to occur as a result of several mechanisms. Air embolism may potentially occur during intravascular transfusion; however, at our institution a closed circuit transfusion system with a three-way stopcock is used, and the apparatus is flushed with blood at each step of the procedure to avoid air leakage. Another potential explanation of vascular accidents might be that of microemboli from transfused blood; however, we minimize this risk by filtering the packed red blood cells twice before transfusion. Alterations in regional blood flow during these procedures may theoretically occur. Two mechanisms that are potentially contributory to the development of the porencephalic cyst in our case include the dramatic increase in blood viscosity and concommitant fetal bradycardia. In the adult, blood hyperviscosity is a recognized cause of cerebral ischemia and infarction.[1] In addition, fetal bradycardia encountered during the intravascular transfusion in our case may have contributed to the cerebrovascular event by producing hypotension, sluggish blood flow, and markedly reduced cerebral perfusion.

Controversy exists with regard to the optimal method of transfusion for hemolytic disease of the fetus. Some centers use only the intravascular method, routinely transfusing packed red blood cells to target hematocrit values of at least 55%.[2] We routinely use the intravascular technique, achieving hematocrit values in the range of 35% to 40%, followed by a standard intraperitoneal transfusion to lengthen the interval between procedures.

Until more data concerning the effects of relative hyperviscosity on fetal organ perfusion become available, we recommend intravascular transfusion of blood to physiologic hematocrits. A combined technique of intrauterine transfusion that includes the intraperitoneal transfusion may be used effectively to allow prolonged intervals between successive transfusions.

Hyporegenerative anemia associated with intrauterine transfusion in rhesus hemolytic disease

James A. Thorp, MD, Timothy O'Connor, MD, John Callenbach, MD, Gary R. Cohen, MD, John D. Yeast, MD, James Albin, MD, and Fred Plapp, MD, PhD
Kansas City, Missouri

Serial erythropoietin and ferritin levels were monitored in a fetus and newborn requiring three intravascular transfusions (in utero) for severe Rh disease. The newborn had a hematocrit of 37% at birth; however a hyporegenerative transfusion-dependent anemia developed and lasted approximately 3 months. The prolonged hyporegenerative anemia may be caused in part by erythropoietin suppression as a result of the fetal intravascular transfusions. In addition, anti-D antibody may also contribute to this anemia by a direct toxic effect on erythroid precursors and by peripheral hemolysis of reticulocytes. (AM J OBSTET GYNECOL 1991;165:79-81.)

Key words: Intravascular transfusion, erythropoietin, hyporegenerative anemia, Rh disease

Severe hemolytic disease of the fetus has declined in frequency over the past two decades because of successful prevention with Rh immune globulin. Unfortunately, this disease continues to be seen with regularity. Intravascular fetal transfusion in lieu of intraperitoneal transfusion has become the technique of choice for treating severe hemolytic disease of the fetus.[1] Hyporegenerative anemia of the newborn after intravascular transfusion for treatment of severe hemolytic disease of the fetus is seen frequently at our institution. Observed after fetal intravascular transfusion, this anemia is delayed in onset until the second to fourth week of life and is associated with low reticulocyte counts. The pathogenesis of this hyporegenerative anemia is unknown; however, both immune injury to the bone marrow[2] and erythropoietin suppression[3] are implicated. We therefore studied serial erythropoietin levels and antibody titers in a newborn who underwent three intravascular transfusions in utero and remained transfusion dependent for 12 weeks after birth.

Material and methods

Informed consent was obtained before samples were taken from the fetus or newborn. Percutaneous umbilical blood sampling and fetal intravascular transfusions were performed under ultrasonographic guidance using standard techniques. Serum erythropoietin and ferritin levels were performed by radioimmunoassay (Smith-Kline Laboratories, Van Nuys, Calif.), and the hemoglobin, hematocrit, reticulocyte counts, and anti-D antibody titers (indirect antiglobulin test) were measured with standard techniques. All samples for erythropoietin, ferritin, and anti-D titers were frozen at −70° F and assayed simultaneously.

Case report

A 27-year-old white woman, gravida 2, para 1, was noted to have a maternal serum anti-D titer of 64 and an anti-C titer of 32 at her first prenatal visit; therefore she had follow-up with serial amniocentesis. The cause of her sensitization was uncertain, because she received both antepartum and postpartum Rh immune globulin in her first pregnancy and had never received blood products. At 28 weeks' gestation, the anti-D titer was 128, and the optical density at 450 nm rose sharply into zone III of the Liley curve. Therefore a percutaneous umbilical blood sampling procedure and possible fetal transfusion were planned. A percutaneous umbilical blood sampling procedure was performed through an anterior placenta and demonstrated the following results on fetal blood: hematocrit, 26%; erythropoietin level, 4 mU/ml; fetal blood type, O Rh positive; and direct antiglobulin test, positive. Unfortunately, reticulocyte counts were not obtained on fetal blood. An intravascular transfusion of 36 ml of type O Rh-negative, cytomegalovirus-negative, irradiated, packed erythrocytes was performed and resulted in a final hematocrit of 36%.

By 30 weeks' gestation the anti-D titer rose to 16,384, and ascites had developed in the fetus. Presumably the significant rise in the anti-D antibody titer was the result of an anamnestic immune response, which was caused by a fetomaternal hemorrhage from the initial transfusion. A repeat percutaneous umbilical blood sam-

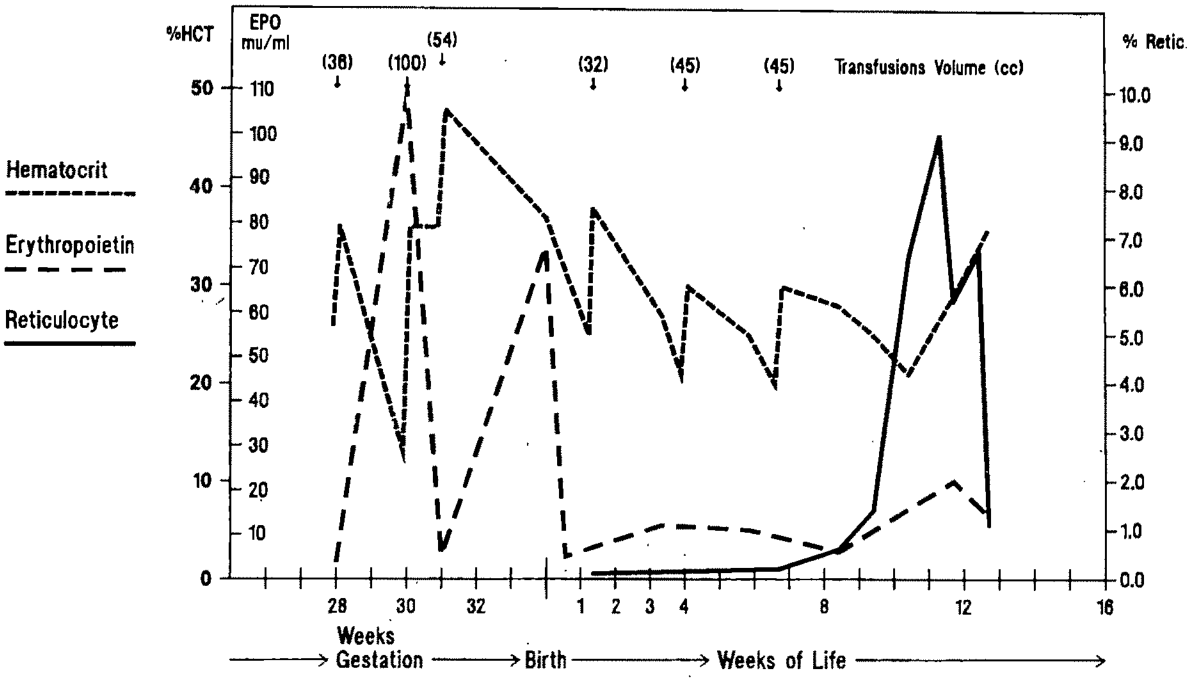

Fig. 1. Severe transfusion-dependent hyporegenerative anemia after intravascular transfusion for rhesus hemolytic disease of fetus. Erythropoietin levels *(EPO)*, milliunits per milliliter, hematocrit (percent), and reticulocytes (percent) are depicted in fetus from 28 weeks until birth and in newborn from birth to 12 weeks. *Arrows* (top of graph) depict transfusion volumes in fetal and newborn periods. Severe Rh disease in this pregnancy necessitated three intravascular transfusions and early delivery at 34 weeks' gestation. At birth cord blood consisted of 100% type O, Rh-negative adult donor blood, with absence of fetal blood cells by the Kleihauer-Betke method. Severe transfusion-dependent hyporegenerative anemia ensued with inappropriately low reticulocyte counts and erythropoietin levels. Three neonatal transfusions were necessary until erythropoietin levels and reticulocyte counts increased by 12 weeks after birth.

pling procedure revealed a fetal hematocrit of 13% and an erythropoietin level of 109 mU/ml. An intravascular transfusion with 100 ml of similarly prepared donor blood resulted in a hematocrit of 36%. After the transfusion, the percentage of fetal cells in the fetal blood sample was 0.5% by the Kleihauer-Betke method.

A third percutaneous umbilical blood sampling procedure was performed at 32 weeks' gestation, revealing a fetal hematocrit of 36% and an erythropoietin level of 5 mU/ml. An intravascular transfusion of 54 ml of similarly prepared donor blood resulted in a hematocrit of 48%.

At 34 weeks' gestation the fetus was in a breech presentation, the amniotic fluid volume was diminished, and a mature phospholipid profile was present. Cesarean section resulted in a vigorous and healthy appearing male infant weighing 2240 gm and having no physical manifestations of rhesus hemolytic disease. The cord blood was type O, Rh negative, and fetal cells were absent by the Kleihauer-Betke test. The erythropoietin level on the cord blood was 75 mU/ml and the initial hematocrit of the infant was 37%. The infant appeared healthy, except for hyperbilirubinemia that necessitated phototherapy and reached a peak of 11 mg/dl on the third day of life.

On day 4 of life, the erythropoietin level had dropped to 5 mU/ml, and by the ninth day of life the infant had tachycardia, poor feeding, and pallor. At that time the hematocrit was 25% with a reticulocyte count of 0.1%; he was given a simple transfusion of 32 ml (approximately 15 mg/kg) of type O, Rh-negative blood, which resulted in resolution of his symptoms. During the next 2 months anemia recurred and was marked by low reticulocyte counts and symptoms of cardiovascular compromise, necessitating two additional transfusions (Fig. 1). By 3 months of age the erythropoietin level rose to 22 mU/ml, and the hematocrit and reticulocyte levels recovered. He was feeding and growing normally.

The fetal and newborn serum anti-D titers (indirect globulin tests) were as follows: 16 at 28 weeks' gestation, 32 at 30 weeks' gestation, 128 at 31 weeks' gestation, 1024 at birth, 512 at 3 days of life, 128 at 3 weeks of life, 1 at 6 weeks of life, and 1 at 14 weeks of life. Serum ferritin levels were measured periodically and gradually increased from 170 ng/ml at 28 weeks' gestation to 672 ng/ml at birth. At 3 weeks of life the ferritin rose to 984 ng/ml.

Comment

Delayed anemia in infants with Rh hemolytic disease is well described in the literature[1-6] before 1963 when intrauterine (intraperitoneal) transfusions were first reported. Dillon and Krivit[4] performed serial bone marrow examinations in 14 newborns with Rh hemolytic disease, and in only one case did the normoblast counts fall below the normal range, suggesting a hypoplastic marrow. In this one case[4] the infant had received three exchange transfusions in the early newborn period. The majority of their cases[4] (13/14) were associated with normoblastic hyperactivity in the bone marrow. These authors and other[5, 7] have suggested that this delayed anemia may be related to many factors, including peripheral hemolysis of fetal Rh-positive cells, a reduced survival of donor Rh-negative cells, and rapid body growth.

Burk et al.[8] described a newborn with severe Rh disease (requiring three intrauterine transfusions) who experienced transfusion-dependent anemia for 12 weeks after birth. These authors did not specify whether the intrauterine transfusions were performed by the intraperitoneal or the intravascular route. At 7 weeks after birth the baby had severe anemia (hemoglobin, 4.5 gm/dl) and a low reticulocyte count (0.1%). Therefore a bone marrow aspiration was performed. This demonstrated many normoblasts; however, there were no reticulocytes. An eluate prepared from the bone marrow erythrocyte precursor cells contained anti-D antibody. These authors[8] concluded not only that the antibody was of sufficient titer to support a hemolytic process but also that it affected bone marrow precursors, leading to an apparent failure of reticulocytosis. The infant had an Rh-negative blood type with a negative direct but positive indirect Coombs' test (anti-D titer was 128). This suggested that only adult Rh-negative cells from previous transfusions survived in the infant's peripheral circulation.

Koenig et al.[3] reported decreased serum erythropoietin levels in an infant with Rh hemolytic disease and hyporegenerative anemia. The fetus had received two intravascular transfusions at 26 and 31 weeks' gestation and was delivered with hydrops at 32 weeks' gestation. At 2 weeks of life the newborn had a hematocrit of 29% and absence of reticulocytes; by 4 weeks of life a hematocrit of 17% prompted a transfusion. These investigators also speculated that reduced erythropoietin concentrations contributed to the anemia in this newborn. Our data also are consistent with those of Koenig et al.,[3] demonstrating an inappropriately low erythropoietin level in the presence of severe newborn anemia. One would expect a very high erythropoietin level if the anti-D antibody were the only cause of this prolonged anemia. Thus there appear to be at least three mechanisms involved in this anemia: anti-D destruction of bone marrow precursors, anti-D destruction of reticulocytes in the peripheral circulation, and an inappropriately low erythropoietin level.

As with other anemias in newborns, iron deficiency does not appear to be a cause of hyporegenerative anemia, as evidenced by the high ferritin levels in this case. Fetal serum ferritin levels appear to rise dramatically in response to intrauterine transfusion. Likewise, the newborn with hyporegenerative anemia also is observed to have high ferritin levels. This reflects both an increase in total iron load as a result of transfusions and a reduced ferritin use as a secondary consequence of erythropoietin suppression.

The findings in this case and in previous reports support future study of recombinant erythropoietin, alone or in combination with exchange transfusion, as a treatment for prolonged hyporegenerative anemia after multiple intrauterine transfusions.

Daily administration of the progesterone antagonist RU 486 prevents implantation in the cycling guinea pig

Marcelo C. Batista, MD,[a] Teresa L. Bristow, BA,[a] Jeselle Mathews, MD,[a]

Bethesda, Maryland

Since progesterone is required to prepare the endometrium for implantation of an embryo, a progesterone antagonist may inhibit nidation and thus prevent pregnancy. We addressed this possibility in the guinea pig, the small laboratory animal whose reproductive physiology most resembles that of women. Daily administration of the antiprogestin RU 486 (0, 1, 2, or 3 mg/kg, subcutaneously) for 9 days after mating inhibited implantation in a dose-dependent fashion. When this compound was given daily throughout the estrous cycle, cyclic vaginal changes, ovulation, and mating were suppressed in up to 17%, 28%, and 55% of animals, respectively. Two of seven mated female animals receiving RU 486, 1 mg/kg/day, had implantation sites. Nidation was completely blocked at higher doses. Thus daily antiprogestin administration prevented pregnancy in sexually active, normally cycling guinea pigs. A similar strategy using a daily antinidatory dose of an antiprogestin may offer a novel approach to human fertility control. (AM J OBSTET GYNECOL 1991;165:82-6.)

Key words: RU 486, guinea pig, contraception, implantation

There is a great worldwide need for the development of new contraceptive agents for population control. One attractive strategy is to interdict implantation without suppressing ovulation or steroidogenesis. Since progesterone is required for the differentiation of the endometrium in preparation for pregnancy,[1] we hypothesized that interruption of the action of progesterone might create a hostile endometrium that is incapable of accepting an embryo. Synthetic steroids that competitively antagonize progesterone at its receptor may thus offer a novel approach to fertility control.

To address this possibility, we investigated the effects of continuous daily administration of RU 486, a progesterone antagonist with very little progestational activity,[2] on the reproductive function of the guinea pig. Since our goal was to develop a human contraceptive agent, we chose to study an animal whose reproductive physiology was similar to that of women. Among the small laboratory animals, the guinea pig best fits this criterion. The guinea pig ovulates spontaneously and has a 16-day estrous cycle, a prolonged luteal phase as a result of an actively secreting corpus luteum, and a hemochorial placentation that is dependent on progesterone.[3, 4] Its reproductive cycle can be timed conveniently by examination of the vaginal membrane, which opens at the time of estrus and ovulation.[5]

Material and methods

Guinea pigs. This study was approved by the Animal Care and Use Committee of the National Institute of Child Health and Human Development. Male and female Hartley guinea pigs (Charles River Breeders, Wilmington, Mass.) weighed 900 to 1200 and 550 to 950 gm, respectively, at the beginning of the studies. They were kept at room temperature (20° to 22° C) under controlled light conditions and had free access to pelleted food and tap water, according to National Institutes of Health guidelines.

Preparation of RU 486. RU 486 was obtained as micronized powder from Roussel-Uclaf (Paris). It was injected subcutaneously daily at 8 to 10 AM in 0.1 to 0.2 ml of a benzyl benzoate and castor oil (1:2.5, vol/vol) solution. Control animals received oil vehicle only.

Procedures. The aspect of the vaginal membrane was examined daily at 8 to 10 AM. When the membrane was fully open, vaginal smears were taken by irrigating the vagina with a few drops of saline solution. The unstained cells were examined under a microscope and

categorized according to the description of Young.[5] The day of leukocytic infiltration after a cornified smear, designated cycle day 1, normally follows ovulation within 24 hours. Blood drawing and intravascular injections were performed by puncture of the anterior vena cava or right ventricle with the animal under anesthesia with ketamine hydrochloride (25 mg/kg intraperitoneally) and xylazine (5 mg/kg intraperitoneally). Plasma was stored at −20° C for later progesterone measurements. Fifteen minutes before the animal was put to death, 1 ml of Evans blue dye 1% was injected intravascularly to facilitate the detection of implantation sites.[6] The animals were killed with carbon dioxide. The number of implantation sites and corpora lutea were determined by visual inspection of the uteri or by examination of the ovaries under a dissecting microscope.

Study 1: Effects of postcoital administration of RU 486. The first study evaluated the ability of postcoital administration of RU 486 to prevent implantation. All animals were acclimatized initially to a 14-hour-light/10-hour-dark cycle (lights on at 7 AM). Female animals were chosen for the study if they had a previous 13- to 17-day cycle, as determined by two subsequent openings of the vaginal membrane. They were individually caged with a male 4 to 5 days before the next expected opening of the vaginal membrane and checked daily at 8 to 10 AM for signs of mating. The day after copulation, designated postcoital day 1, was documented by the presence of a copulatory plug or by the presence of spermatozoa in the vaginal smear. RU 486 was given in single daily doses of 0, 1, 2, or 3 mg/kg for the first 9 days after mating to groups of 10 female animals. Progesterone was measured on postcoital days 7 and 10 and necropsy was performed on day 10.

Study 2: Effects of precoital administration of RU 486. The second study extended RU 486 treatment to the entire cycle before mating and evaluated its effects on sexual behavior, ovarian activity, and implantation rate. All animals were acclimatized initially to an inverted 14-hour-light/10-hour-dark cycle (lights on at 8 PM). Females with a previous 15- to 17-day estrous cycle were randomized to four groups of 12 animals. RU 486 injections (0, 1, 2, or 3 mg/kg/day, subcutaneously) were begun on cycle day 2 and continued until 1 day before the animal was put to death. Progesterone was measured on cycle day 8. Two days later, each female was caged with a male of proved fertility. An intensive search for copulatory evidence was then undertaken, because our previous study had shown that these signs were often missed if animals were checked only once daily. Accordingly, female animals were examined every 2 hours (8 AM to 8 PM) for the presence of a copulatory plug and twice daily (8 AM and 8 PM) for spermatozoa in the vaginal smear. Mated and unmated females were put to death 11 days after copulation or after closure of the vaginal membrane, respectively. Animals without opening of the vaginal membrane were killed on the thirty-sixth day of RU 486 administration.

Hormone assays. The plasma concentrations of progesterone were measured by radioimmunoassay.[7] All samples from each study were measured in one assay; the intraassay coefficient of variation was ≤12%.

Statistical analysis. All results are expressed as mean ± SE. Data were analyzed by means of one-factor analysis of variance. Differences were considered significant at a p level of <0.05.

Results

Study 1: Postcoital administration of RU 486. RU 486, 3 mg/kg/day, completely inhibited nidation (Table I). Only 4 of 10 animals receiving 2 mg/kg/day had implantation sites, a significant reduction ($p = 0.0214$) in the implantation rate (80%) seen in the control group. There were no differences among groups in the number of corpora lutea, suggesting similar ovulatory

rates in all animals. Progesterone concentrations were similar on postcoital day 7 in all groups but were significantly reduced ($p = 0.004$) on postcoital day 10 in animals receiving RU 486 at a dose of 3 mg/kg/day.

Study 2: Precoital administration of RU 486. Daily administration of RU 486 throughout the estrous cycle prevented cyclic vaginal changes in one to three animals at each dose (Table II). No mating occurred and no corpora lutea were seen in these females.

All other animals exhibited openings of the vaginal membrane associated with typical changes of the vaginal smear. RU 486 at a dose of 1 or 2 mg/kg/day did not affect the length of the cycle, as determined by the number of days elapsed between either two subsequent openings of the vaginal membrane or two subsequent leukocytic smears (Table II). However, the cycle was significantly shortened in animals treated with 3 mg/kg/day as compared with female controls. Progesterone levels on cycle day 8 were similar in all groups (Table II).

One or two animals in each RU 486–treated group had cyclic vaginal opening but lacked corpora lutea (Table II). When present, the number of corpora lutea in each animal decreased significantly with RU 486 administration at a dose of 2 mg/kg/day (2.8 ± 0.2, $p = 0.0031$) and 3 mg/kg/day (2.7 ± 0.3, $p = 0.0031$) compared with vehicle administration (3.5 ± 0.9).

Mating of cycling females was progressively inhibited as the dose of RU 486 was increased, occurring in 92% of the control group, 78% of the animals receiving 1 mg/kg/day, and 40% to 45% of those treated with the two higher doses of RU 486. Copulatory signs were more common in RU 486–treated females with corpora lutea (58%) than in those without corpora lutea (10%).

Nine of 11 mated control animals had implantation sites, as compared with two of seven mated females treated with RU 486, 1 mg/kg/day. RU 486 completely inhibited nidation in the nine mated animals receiving 2 or 3 mg/kg/day.

Comment

Our first study demonstrated that postcoital administration of RU 486, 3 mg/kg/day, completely inhibited implantation in the guinea pig. This antinidatory property of RU 486 probably derives from blockade of progesterone action on the endometrium. In addition, the late luteolytic action of this compound may contribute to the functional deficiency of progesterone induced by RU 486 at the receptor level. Others have shown that progesterone is required for implantation in the guinea pig, because oophorectomy performed within 2 days of mating prevents pregnancy.[4] In addition to its effects on the endometrium and ovary, RU 486 may alter tubal transport and cause the egg to reach the uterine cavity at a time when the endometrium is refractory to implantation. Both accelerated transport of ova as a result of RU 486 treatment[8, 9] and the existence of a short phase of endometrial receptivity to nidation[10] have been reported in the rat. It is also possible that RU 486 prevents implantation in the guinea pig by inhibiting embryonic development. In other rodents, precoital or postcoital administration of RU 486 resulted in the loss of a large number of embryos because of either early expulsion or destruction of eggs. These effects may derive from a direct action of RU 486 on either the reproductive tract of the mother or the cleavage-stage embryo.[8, 11, 12]

In our second study RU 486 administration completely inhibited opening of the vaginal membrane and ovulation in 17% and 28% of the animals, respectively, regardless of the dose used. At doses of 2 or

3 mg/kg/day, the compound also decreased the total number of corpora lutea in each animal. These effects may reflect suppression of gonadotropin secretion, resulting in disrupted folliculogenesis and ovarian steroidogenesis, and may be analogous to the inhibition of follicular development and steroidogenesis seen with follicular phase administration of RU 486 to women.[13, 14] In particular, estrogen plays an important role in the opening of the vaginal membrane[15] and in the initiation of the preovulatory luteinizing hormone surge in the guinea pig.[16]

The length of the estrous cycle decreased when RU 486 was given at a dose of 3 mg/kg/day, an effect similar to the one observed after luteectomy.[17] This may represent an action of RU 486 to reverse the progesterone inhibition of gonadotropin secretion and thus accelerate folliculogenesis and ovulation.

Mating was inhibited in a dose-dependent fashion by preovulatory administration of RU 486. A similar inhibition of sexual behavior was observed with RU 486 administration to oophorectomized, estrogen-primed guinea pigs treated with progesterone.[18] These results, together with the finding that progesterone concentrations rise during estrus, strongly support the concept that estrus is induced by progesterone after adequate estrogen priming.[19-21] This compound also seemed to dissociate estrus from ovulation, because roughly half of the treated animals ovulated but did not mate and a few females mated without ovulating.

Precoital administration of RU 486 prevented pregnancy in 14 of 16 mated guinea pigs. In contrast to the dose-response results seen with postcoital administration of this compound, implantation was completely blocked at a dose of 2 mg/kg/day. This suggests that RU 486 has a cumulative effect when given for a more extended period of time or, alternatively, that it inhibits fertilization. However, the compound does not affect fertilization of the egg in mice.[12]

The antifertility properties of RU 486 observed in the guinea pig may be extrapolated to other species, such as the human, that also require progesterone for the differentiation of the endometrium and implantation.[1] So far, the contraceptive efficacy of RU 486 in women has been assessed by giving the compound at a large single dose in the mid or late luteal phase. Although RU 486 consistently induced menses within 72 hours of its administration in women not at risk for pregnancy,[22, 23] it failed to prevent pregnancy in 18.8% of women having unprotected intercourse.[24] No clinical trials have been conducted to test the ability of RU 486 to interdict implantation when given throughout the cycle.

In summary, our studies show that daily administration of RU 486 can prevent pregnancy in sexually active, ovulatory guinea pigs. These results suggest a novel use for antiprogestin compounds taken as daily contraceptive agents to prevent nidation in women. However, mating behavior and ovarian activity were inhibited in a significant number of RU 486–treated animals. Thus, before a similar contraceptive trial can be conducted in women, the ability of RU 486 to disrupt endometrial maturation without significantly affecting other reproductive function must be evaluated.

We thank Mr. Art Tanner, Mr. Michael Trumball, Ms. Nathalie Strother, Ms. Laura Shell, and Ms. Quita Bowman for technical assistance. We also appreciate the gracious gift of RU 486 from Roussel-Uclaf.

Fetal heart rate response to vibroacoustic stimulation during low and high heart rate variability episodes in late pregnancy

John A.D. Spencer, MB, BS, Anne Deans, MB, BS, Peter Nicolaidis, MD, and Sabaratnam Arulkumaran, MD
London, England

In 52 women in late pregnancy, the mean durations of transient fetal tachycardia after vibroacoustic stimulation during low fetal heart rate variability (4.8 minutes) and high fetal heart rate variability (6.3 minutes) were similar. The fetal heart rate continued with high variability in all cases, suggesting that the fetus did not return to its prestimulation state after vibroacoustic stimulation during quiescence. In 10 women, the duration of high variability after vibroacoustic stimulation during low fetal heart rate variability was significantly shorter (mean, 22 minutes) than the preceding (mean, 36 minutes) or subsequent (mean, 43 minutes) high-variability components of complete rest activity cycles. In another 10 women, the duration of high variability after vibroacoustic stimulation during high fetal heart rate variability was similar to preceding and subsequent high-variability episodes. In these 20 women, the next complete rest-activity cycle after vibroacoustic stimulation was not different in duration to the complete cycle recorded on the previous day. (AM J OBSTET GYNECOL 1991;165:86-90.)

Key words: Vibroacoustic stimulation, fetal heart rate variability, fetal behavioral cycles

The normal baseline fetal heart rate (FHR) in late pregnancy is characterized by alternating episodes of low and high FHR variability[1, 2] that accompany quiet and active behavioral states in the fetus.[3] Such variability changes have been used to study fetal behavior in late pregnancy,[4, 5] during labor,[6] and in the newborn.[7, 8] In the term fetus, vibroacoustic stimulation during fetal quiescence resulted in a transient increase in baseline FHR (tachycardia) for up to 15 minutes.[9-11] with an increase in the frequency and size of accelerations, associated with an increase in fetal movements, for up to 1 hour.[9, 12, 13] The extent to which this abrupt change in the level of arousal,[14] likened to a startle response,[15] interrupts the natural cycle of fetal behavioral states is unknown. To assess the degree of fetal disturbance after vibroacoustic stimulation we compared the FHR response to stimulation during low FHR variability with the response obtained to stimulation during high FHR variability. We also compared complete cycles of low and high FHR variability episodes

before vibroacoustic stimulation with the type and duration of poststimulation variability as well as the next complete cycle of low and high FHR variability episodes after vibroacoustic stimulation.

Material and methods

Fifty-two women with singleton pregnancies between 36 and 42 weeks' gestation, all with a cephalic presentation, were studied after antenatal admission to Queen Charlotte's and Chelsea Hospital. The reasons for admission were postmaturity (8), suspected intrauterine growth retardation (6), mild pregnancy-induced hypertension (10), social problems (3), placenta previa (6), planned elective lower segment cesarean section (11), and other reasons (8). Only women who reported normal fetal movements were included in the study. No study participants were taking medication or were smokers. Informed consent was obtained from each woman and the study was approved by the hospital ethics committee.

Studies were performed at the same time each morning to exclude the effects of diurnal rhythms. The FHR was recorded with a pulsed Doppler ultrasonographic transducer and an FM7 fetal monitor (Oxford Sonicaid, Chichester, United Kingdom). The mother was semirecumbent and in a quiet room. After 10 minutes of FHR record a vibroacoustic stimulator (Corometrics) was placed on the maternal abdomen over the fetal vertex and activated for 5 seconds.[9, 12, 13] In 25 cases vibroacoustic stimulation was applied after 10 minutes of low FHR variability and in 27 cases it was applied after 10 minutes of high FHR variability. The FHR record was continued until the poststimulation episode of FHR variability changed. In a subgroup of 20 women a long FHR record was made without vibroacoustic stimulation on the first morning to obtain a complete behavioral cycle, as indicated by consecutive low and high FHR variability episodes. The next morning, at the same time, vibroacoustic stimulation was applied after 10 minutes of low FHR variability in 10 women and after 10 minutes of high FHR variability in the other 10 women. These FHR records were then continued until the next complete cycle of low and high FHR variability episodes was obtained after the poststimulation episode.

Low FHR variability episodes were defined as periods of at least 5 minutes' duration with a stable FHR baseline, decreased baseline (long-term) variability (amplitude less than 10 beats/min) and few or no FHR accelerations (FHR pattern A associated with fetal state 1F, quiescence[3]). High FHR variability episodes were identified when the baseline FHR variability was greater than 10 beats/min amplitude with accelerations (FHR pattern B associated with fetal state 2F, activity[3]). Episodes included in the study were complete in that they were preceded and followed by a change from one level of variability to another. All durations were determined from the FHR trace and measured to the nearest whole minute. An acceleration was defined as an abrupt rise in FHR of more than 15 beats/min, returning toward the baseline again after reaching a peak. Tachycardia was defined as an increase in baseline FHR of more than 15 beats/min for longer than 1 minute.

The amplitude and duration of the initial tachycardia in response to vibroacoustic stimulation and the nature and duration of the variability episode immediately after vibroacoustic stimulation during low FHR variability were compared with the effects of vibroacoustic stimulation during high FHR variability with the unpaired Student t test. In the subgroup of 20 women the mean durations of the prestimulation episodes of low and high FHR variability in a complete cycle were compared with the duration of poststimulation variability after vibroacoustic stimulation and with the episodes in the next complete cycle of FHR variability episodes with the Student paired t test and the Wilcoxon matched-pair, signed-rank test. Significance was accepted when $p < 0.05$.

Results

All fetuses stimulated during low FHR variability responded with a transient baseline tachycardia that continued in high variability after returning to the baseline (Fig. 1). Those stimulated during high FHR variability also showed a similar transient tachycardia and then continued in high variability. The amplitude of the tachycardia rarely exceeded the size of the largest acceleration noted during preceding or subsequent high FHR variability and was similar irrespective of the variability at the time of stimulation (Table I). The mean duration of the tachycardia and the mean duration of high variability heart rate immediately after the tachycardia were similar whether vibroacoustic stimulation was applied during low or high FHR variability (Table I). The baseline FHR after the tachycardia was not significantly different from the baseline rate before stimulation, despite the increased variability and number of accelerations (Fig. 2).

Of the 20 women with long FHR records before vibroacoustic stimulation, the mean durations of high and low FHR variability episodes were not significantly different between the 10 stimulated in low FHR variability and the 10 stimulated in high FHR variability (Table II). The mean duration of high variability (22.8; SD, 11.6; range, 9 to 46 minutes) that followed vibroacoustic stimulation during low FHR variability ($n = 10$) was significantly shorter than the high variability episodes that contributed to the complete cycles in the same women before (36.4; SD, 14.9 minutes; $p < 0.01$) and after (42.8; SD, 20.1 minutes; $p < 0.05$) stimulation. However, the mean duration of high vari-

ability (42.4; SD, 28.2; range, 16 to 109 minutes) after vibroacoustic stimulation during high FHR variability ($n = 10$) did not differ from the prestimulation (50.5; SD, 27.3 minutes) and poststimulation (40.4; SD, 18.2 minutes) high variability episodes in these women. In all 20 cases, the mean durations of low and high FHR variability episodes before stimulation were not significantly different from the mean durations of those in the next complete FHR variability cycle that occurred subsequent to the response episode (Table II). The results of analyses with the Student t test and the Wilcoxon matched-pair test were similar. There was no significant difference in the amplitude of accelerations during the spontaneous high FHR variability episodes before and after stimulation.

Comment

The immediate response to vibroacoustic stimulation by all cases in this study was an abrupt rise in baseline FHR. We consider this a transient tachycardia because it lasted longer than the duration of an acceleration although it always returned to the preceding baseline level within 15 minutes. Previous reports have described this initial response as a significant rise in baseline FHR,[9, 10, 13] a significant increase in mean duration of accelerations,[16] and a tachycardia.[11] We found that the mean amplitude of this response often took the rate above 150 beats/min, the recently proposed upper limit of normal for the FHR,[17] for between 1 and 15 minutes and so we believe that the description of tachycardia is more appropriate. However, contrary to one previous report[16] we found that the mean amplitude of this tachycardia was not greater than the largest of spontaneous accelerations that occurred either before after stimulation. FHR accelerations are known to be associated with spontaneous fetal movements[18] and this supports the idea that the transient tachycardia after vibroacoustic stimulation is associated with an increase in fetal movements, consistent with the awake fetal state.[3] However, because this may be brief (Fig. 2), some methods of analysis have failed to show an increase in fetal movements.[10, 12] One study with ultrasonography found a fetal startle response each time after vibroacoustic stimulation.[15] All fetuses in our study responded to vibroacoustic stimulation.

We found the duration of transient tachycardia after vibroacoustic stimulation during low FHR variability to be similar to that reported previously.[9, 10] It is of interest that both amplitude and duration of the tachycardia after stimulation during high FHR variability were sim-

ilar to that after vibroacoustic stimulation during low FHR variability, indicating that this aspect of the fetal response to vibroacoustic stimulation did not depend on the preexisting FHR variability. Devoe et al.[19] also reported that all fetuses responded to vibroacoustic stimulation with a brief tachycardia irrespective of the preexisting state. The sudden and abrupt change in FHR has led to the suggestion that the fetus actually wakes up (state 4F[3])[19] and this is supported by the fact that the mother feels vigorous fetal movements[11, 12, 15] associated with the sustained but transient tachycardia (FHR pattern D according to Nijhuis et al.[3]). The initial FHR response to vibroacoustic stimulation can therefore be explained by the abrupt transition into a transient period of wakefulness; our findings confirm that this response also follows vibroacoustic stimulation when applied during high FHR variability.

It is generally accepted that episodes of high FHR variability represent the active sleep state in the fetus (state 2F) and these alternate with episodes of low FHR variability, representing periods of quiet sleep (state 1F) to characterize most of the continuous FHR record after 36 weeks' gestation.[1, 4, 20] The duration of the second component of the fetal response to vibroacoustic stimulation applied in low FHR variability, namely the continuation in high variability, has not been previously reported. Persistance of body movements and a raised computer-derived baseline FHR for up to 1 hour have been described.[12, 13] We found that all fetuses, whether stimulated during low or high variability, continued in high variability after vibroacoustic stimulation. Thus after the initial response to stimulation, all fetuses remained in state 2F and the duration was similar irrespective of the variability at the time of vibroacoustic stimulation. Therefore it would seem that when stimulated into wakefulness from active sleep the fetus returned to this state but when stimulated into wakefulness from quiet sleep the fetus did not return to the quiet sleep state but remained in active sleep. Thus alteration of fetal behavioral states is greater after vibroacoustic stimulation during low FHR variability.

The 20 women in the subgroup studied on 2 consecutive days were selected because they had a complete cycle of FHR episodes within the 120-minute record made on the first occasion. Therefore the mean durations of consecutive low and high FHR variability episodes shown in Fig. 2 are shorter than some previous reports[1, 6] but are similar to others derived from shorter records.[18] However, each of these 20 women acted as her own control for the comparison between complete cycles before and after vibroacoustic stimulation and for the comparison between high variability episodes before and after with the duration of high variability that followed the transient tachycardia. Our results show that vibroacoustic stimulation during high variability resulted in a duration of poststimulation high variability similar to the durations of high variability episodes during behavioral cycles before and after stimulation. However, the duration of high variability after vibroacoustic stimulation during low variability was significantly shorter than the prestimulation and poststimulation high variability components of complete rest-activity cycles, suggesting that the active fetal state after the abrupt transition from quiescence to wakefulness may not be the same as the spontaneous episodes of fetal activity that contribute to rest-activity cycles. The next complete spontaneous behavioral cycle was of similar duration to the cycle recorded on the previous day, indicating that the disruption of fetal behavior did not extend beyond the stimulated cycle.

In conclusion, our findings agree with previous studies that indicate that vibroacoustic stimulation during low FHR variability produces an abrupt change from quiet to active fetal state through a transient period of wakefulness. In addition, we have shown that the fetal response to vibroacoustic stimulation during high FHR variability is a similar transient period of wakefulness before resumption of the preexisting active state. Although we have shown that disruption of fetal rest-activity cycles does not extend beyond the stimulated cycle, we do not believe that this implies safety. The value of vibroacoustic stimulation as a means of antenatal fetal investigation needs to be investigated in the form of a randomized trial relating to neonatal outcome and not solely to the production of a reactive FHR record, which it does quite effectively.[21]

Elective versus emergency cesarean hysterectomy cases in a residency program setting: A review of 129 cases from 1984 to 1988

Whitney Gonsoulin, MD, Rose T. Kennedy, MD, and Kathy H. Guidry, MD
New Orleans, Louisiana

A retrospective study was performed to compare elective versus emergency cesarean hysterectomy in a residency program. We noted the following statistically significant differences between emergency and elective cases: (1) Estimated blood loss (mean ± SD) for emergency and elective cases was significantly different at 1495 ± 772 and 875 ± 396 ml ($p = 0.001$). (2) Operative time in emergency cases was significantly longer than in elective cases (105 ± 38 vs 83 ± 27 minutes, $p = 0.003$). (3) The incidence of transfusion was 68% in our emergency cases and 14.6% in the elective series ($p < 0.05$). (4) Febrile morbidity in our series was 40% in emergency cases and 18.3% in elective cases ($p < 0.05$). Our series was comparable to previous series reported. Our experience suggests that cesarean hysterectomy can be performed safely in a residency training program when done as an elective procedure in the well-prepared patient. (AM J OBSTET GYNECOL 1991;165:91-4.)

Key words: Cesarean hysterectomy, operative morbidity

Emergency hysterectomy has been accepted as a lifesaving procedure for patients with bleeding at the time of cesarean section. Elective cesarean hysterectomy is considered controversial by many because of concern about increased bleeding, transfusion, and urologic complications. Cesarean hysterectomy may be an alternative to cesarean section and tubal ligation, particularly for those patients with a history of menorrhagia, dysmenorrhea, leiomyomas, or other problems occurring before pregnancy that predict further gynecologic surgery. Cesarean hysterectomy is not offered to patients who are not undergoing a cesarean section for indicated reasons.

This paper reports on emergency versus elective cesarean hysterectomy in a residency program setting. Our outcomes were compared with those of previous studies reported in the literature.

Material and methods

A retrospective chart analysis was undertaken on all cases of cesarean hysterectomy performed between 1984 and 1988. Operations included for review were those performed after 28 weeks of gestation and after abdominal delivery. Hysterectomies performed after vaginal delivery were excluded.

The operations were classified as either *elective indicated* or *emergency*; the latter were performed as a lifesaving procedure to prevent exsanguination in cases of profuse bleeding. Elective cases are considered to be those in which the procedure was planned and performed on patients in whom hysterectomy and cesarean delivery were indicated. Patients in whom the procedure was used to treat severe cervical dysplasia were evaluated by colposcopy during the pregnancy. Patients with leiomyomas that were present and symptomatic during the nonpregnant period were considered elective indicated cesarean hysterectomy.

Our policy was to offer this procedure in a clinic setting, before the stress of labor occurred and where an informed consent could be obtained after the patient had discussed the decision with her partner. These patients were given full explanations of the risks and benefits of this operation as opposed to cesarean section and tubal ligation. A staff physician supervised the cases, but the operations were performed by third- and fourth-year residents. The procedure used was the clamp-cut-and-tie-later technique as advocated by Plauché.[1] Prophylactic antibiotics were used in 82% of cases. Febrile morbidity was defined as two temperatures >38° C that occurred at least 6 hours apart (excluding the first 24-hour postoperative period). Change in hematocrit was calculated as preoperative hematocrit minus the last hematocrit before discharge in patients who did not need transfusion. Blood loss estimations were made by the anesthesia personnel in each case. These procedures were performed at the University Medical Center and at Earl K. Long Hospital, both of

which are affiliated hospitals of Louisiana State University Medical School in New Orleans.

Data are reported as mean ± SD. Groups were compared by unpaired Student *t* tests, with $p < 0.05$ considered significant.

Results

During the 5-year study period there were 33,963 deliveries, 4891 of which were cesarean sections; this resulted in a cesarean section rate of 14.2%. A total of 129 cesarean hysterectomies were performed during the study period; there were 107 elective cases and 22 emergency cases.

Gestational age at delivery was significantly higher for emergency cases than for elective cases (33.5 ± 5.0 and 38.4 ± 1.9 weeks, respectively, $p = 0.001$). Apgar scores at 1 minute of life were 5.5 ± 3.2 and 8.3 ± 1.2 for emergency and elective cases, respectively ($p = 0.001$). Apgar scores at 5 minutes were 6.6 ± 3.2 for emergency cases and 9.0 ± 0.4 for elective cases ($p = 0.001$). Demographic data are summarized in Table I.

Indications for emergency cases are summarized in Table II. Hemorrhage, uterine rupture, and uterine incision dehiscence were the most common indications for emergency cesarean hysterectomy. The majority of cases of uterine rupture, which were associated with fetal distress, occurred before term, whereas three cases of uterine dehiscence (uterine scar separation found incidentally at the time of repeat cesarean section) occurred at term in this series. In all cases the surgeons were able to remove the cervix at the time of hysterectomy.

Table III. Indications for elective indicated cesarean section hysterectomy

Indication	*No.*	*Percentage of total*
Undesired fertility and history of dysmenorrhea and menorrhagia	50	45
Leiomyomas	17	16
Severe cervical dysplasia	15	14
Undesired fertility	11	10
Failed bilateral tubal ligation	7	6
Chronic pelvic pain	4	4
Placenta previa	3	3
Symptomatic descensus	2	2

Table IV. Operative parameters: elective versus emergency cesarean hysterectomy

Parameter	*Emergency (n = 22)*	*Elective (n = 107)*	*p Value*
Operating time (min)	105 ± 38	83 ± 27	0.003
Estimated blood loss (ml)	1495 ± 772	875 ± 396	0.001
Hospital stay (days)	5.5 ± 2.3	4.2 ± 1.8	0.004

The most common indication for elective cesarean hysterectomy was previous cesarean delivery with undesired future fertility, as well as a history of dysmenorrhea and menorrhagia. Other indications included symptomatic leiomyomas, cervical dysplasia, and previous failed tubal ligation. The percentages of each indication for elective cesarean section are given in Table III.

Operative time in emergency cases was significantly longer than in elective cases (105 ± 38 vs 83 ± 27 minutes, $p = 0.003$). Estimated blood loss for emergency and elective cases was 1495 ± 772 and 875 ± 396 ml, respectively ($p = 0.001$). Three elective and four emergency cases required preoperative transfusion. Mean change in hematocrit in those elective cases that did not require transfusion was −3.7% ± 3.6%. Both units of transfusion and length of hospital stay were greater in the emergency cases. All operative parameters are displayed in Table IV.

No maternal deaths occurred in patients undergoing cesarean hysterectomy. Complications at the time of cesarean hysterectomy are summarized in Table V. Infectious morbidity included vaginal cuff cellulitis, pneumonia, and urinary tract infection. Reexploration after cesarean hysterectomy occurred in one emergency case as a result of postoperative bleeding at the vaginal cuff area, which was controlled with suture li-

gation. Other complications are also listed and compared in Table V.

There were several patients who underwent other procedures at the time of cesarean hysterectomy. Unilateral or bilateral salpingectomy and oophorectomy were the most common procedures. Unilateral procedures were performed in cases of bleeding ($n = 12$) or in the presence of adnexal pathologic conditions ($n = 4$). The indication for bilateral salpingectomy and oophorectomy was advanced patient age, with a mean age of 41 ± 1.5 years. Appendectomies were performed when a pathologic condition was present and was confirmed microscopically. Procedures performed at the time of cesarean hysterectomy are shown in Table VI.

Comment

Few obstetricians trained after 1980 have experience in performing cesarean hysterectomy. When the need arises for emergency hysterectomy at the time of cesarean section, physicians are faced with a difficult procedure and an unstable patient.

Before the 1940s the major indications for emergency cesarean hysterectomy were hemorrhage and uterine pathologic conditions such as a ruptured uterus. During the 1960s the indications for cesarean hysterectomy were expanded to include elective sterilization. Indications for cesarean hysterectomy in our study were not different from those reported in recent series.[1-3] Pregnancy after tubal ligation at cesarean section has been reported to occur more frequently than when tubal ligation is done as an interval procedure. The failure rate ranges from 0% for the Uchida[4] and Irving[5] procedures to 1.75% for the Pomeroy procedure.[6,7] These failure rates are related to procedure type and technique.

Table VII compares our series to those of Plauché et al.[1-3] and Barclay et al.[2] The mean operating time of elective procedures in our series was 83 ± 27 minutes. Barclay et al.[2] reported a mean operative time in cesarean section and tubal ligation as 51.1 ± 14.5 minutes. In the cesarean hysterectomy series of Plauché et al.,[1] in which the same surgeons did all procedures, the mean operative time was 65 minutes. We feel that the operative time is not a limiting factor when the surgeons are experienced in the procedure.

The mean blood loss in our series was 875 ± 396 ml. For those who did not need transfusion, the change from preoperative to discharge hematocrit was only −3.7% ± 3.6%. We do not feel that excessive blood loss is a contraindication to cesarean hysterectomy performed by surgeons trained in the procedure.

The incidence of transfusion in our elective series was 14.6% as compared with the elective series of Barclay et al.[2] and Plauché et al.,[1] which were 19.9% and 11.8%, respectively. The lower transfusion rate in the series of Plauché et al. might have been related to the experience level of the surgeons or to the higher presurgery hematocrits of the private patients. In our series the mean preoperative hematocrit of those requiring transfusion was 32.6% ± 5.8%, as compared with 35.9% ± 3.0% in patients who did not need transfusion ($p = 0.001$). This lower starting hematocrit may explain the greater risk of transfusion in this group. The incidence of transfusion in cesarean section is reported as 1% to 6%[8]. The risk of illness from transfusion in elective procedures could be reduced by allowing autologous donations. Recently, we have begun to allow autologous donation in our department for patients anticipating elective cesarean hysterectomy. We recommend that those patients who anticipate cesarean hysterectomy donate 2 units of blood before delivery.

The hospital stay for elective cesarean hysterectomy in this series was 4.2 ± 1.8 days, which is comparable to the hospital stay for cesarean section and tubal ligation.[9] In an indicated hysterectomy, we save the patient the risk of undergoing a second procedure and anesthesia. In the series of Bukovsky et al.,[9] in which hysterectomy was used for sterilization, only one patient needed further gynecologic surgery, as opposed to 49 additional procedures required by 86 matched patients who underwent cesarean section and tubal ligation. Ten of these 86 patients later underwent a hysterectomy. Cesarean hysterectomy may help avoid further surgery in those cases in which hysterectomy is indicated at the time of cesarean section.

Febrile morbidity in our series was 18.3% in elective cases. The series of Barclay et al.[2] had a febrile morbidity of 31%, but this was before the use of prophylactic antibiotics. The private and residency series of Plauché et al.[1, 3] reported incidences of 26.6% and 30.5%, respectively, for febrile morbidity. The incidence of febrile morbidity in cesarean section alone has been reported to range from a low of 5% to a high of approximately 85%, with a mean of 30% to 40%.[10] Cesarean hysterectomy in our series had a lower febrile morbidity rate than did cesarean section alone.[10] This may be because cesarean hysterectomy removes the site of endomyometrial infection.

Urologic injuries have been reported as a complication in other series of elective cesarean hysterectomy. The incidence of urologic injuries after cesarean hysterectomy ranges between 0.3% and 0.9%.[11] Plauché et al.[1] reported two cases of cystotomy and another unrecognized bladder injury with subsequent fistula development in 108 cases of cesarean hysterectomy. Haynes and Martin[12] reported 11 cystotomies and one fistula in 149 cesarean hysterectomies. In our series there was only one incidental cystotomy in a patient with two previous cesarean sections. This injury was repaired without complication. The lower incidence of bladder injury in our series may be related to our adherence to cautious bladder reflection at the time of cesarean section. Our practice was to test the bladder with sterile solution in any cases of suspected bladder injury.

The performance of other procedures at the time of cesarean hysterectomy is determined by pathologic conditions noted at the time of surgery and by the desires of the patient. Oophorectomy may be indicated in those with adhesive disease of the adenexa or as a result of the patient's age. Oophoropexy can be useful in preventing dyspareunia.

Our series suggests that cesarean hysterectomy can be a safe procedure when performed electively in the well-prepared patient. Although the incidence of transfusion is higher than that of cesarean section alone, the benefits to the patient who has an indication for hysterectomy may outweigh the risks of undergoing repeated surgery and anesthesia at a later date. As the rate of cesarean section increases, we must be aware of the options available to women who are undergoing a repeat cesarean section. Surgeons with the required skill can offer a cesarean hysterectomy at the time of repeat cesarean section to those patients with an indication for hysterectomy. Performing elective cesarean hysterectomy prepares the obstetrician for the more difficult procedure of emergency cesarean hysterectomy.

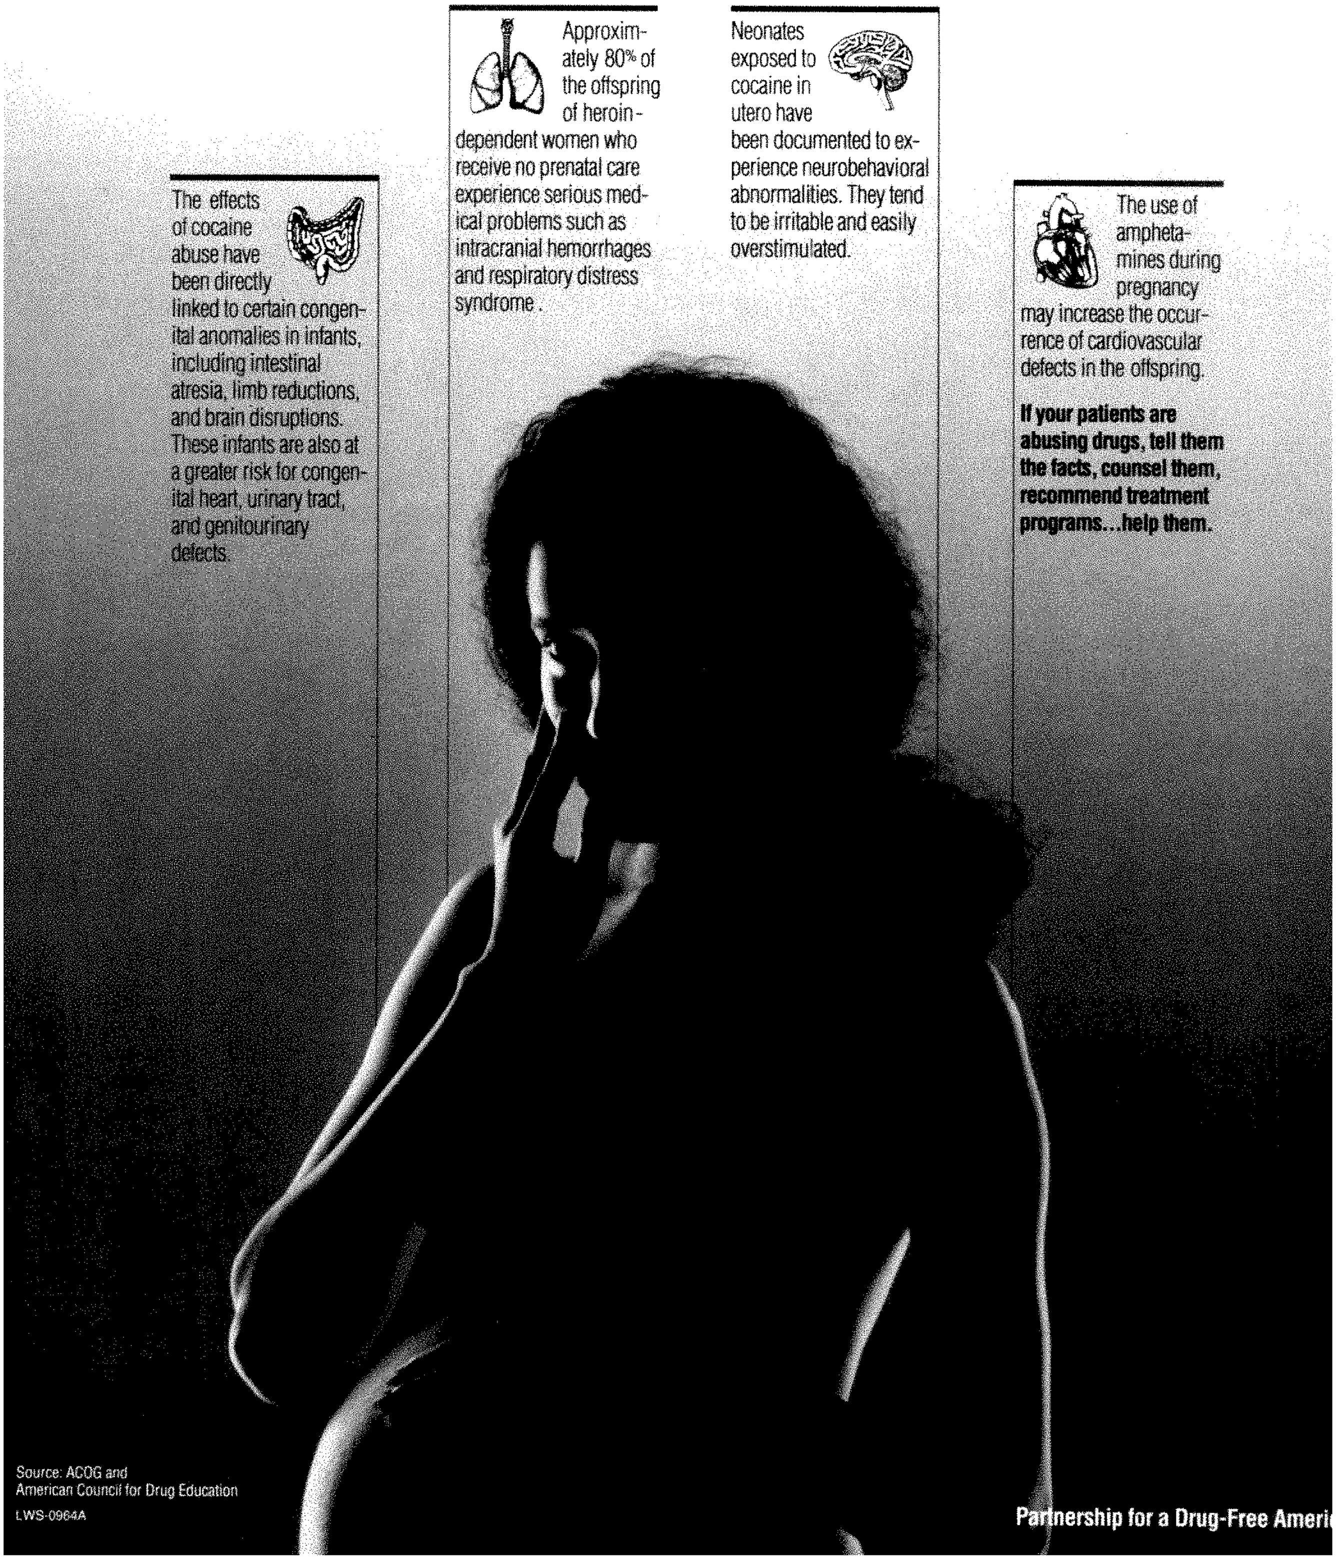
DRUG ABUSE IS CHILD ABUSE



The effects of cocaine abuse have been directly linked to certain congenital anomalies in infants, including intestinal atresia, limb reductions, and brain disruptions. These infants are also at a greater risk for congenital heart, urinary tract, and genitourinary defects.

Approximately 80% of the offspring of heroin-dependent women who receive no prenatal care experience serious medical problems such as intracranial hemorrhages and respiratory distress syndrome.

Neonates exposed to cocaine in utero have been documented to experience neurobehavioral abnormalities. They tend to be irritable and easily overstimulated.

The use of amphetamines during pregnancy may increase the occurrence of cardiovascular defects in the offspring.

If your patients are abusing drugs, tell them the facts, counsel them, recommend treatment programs...help them.

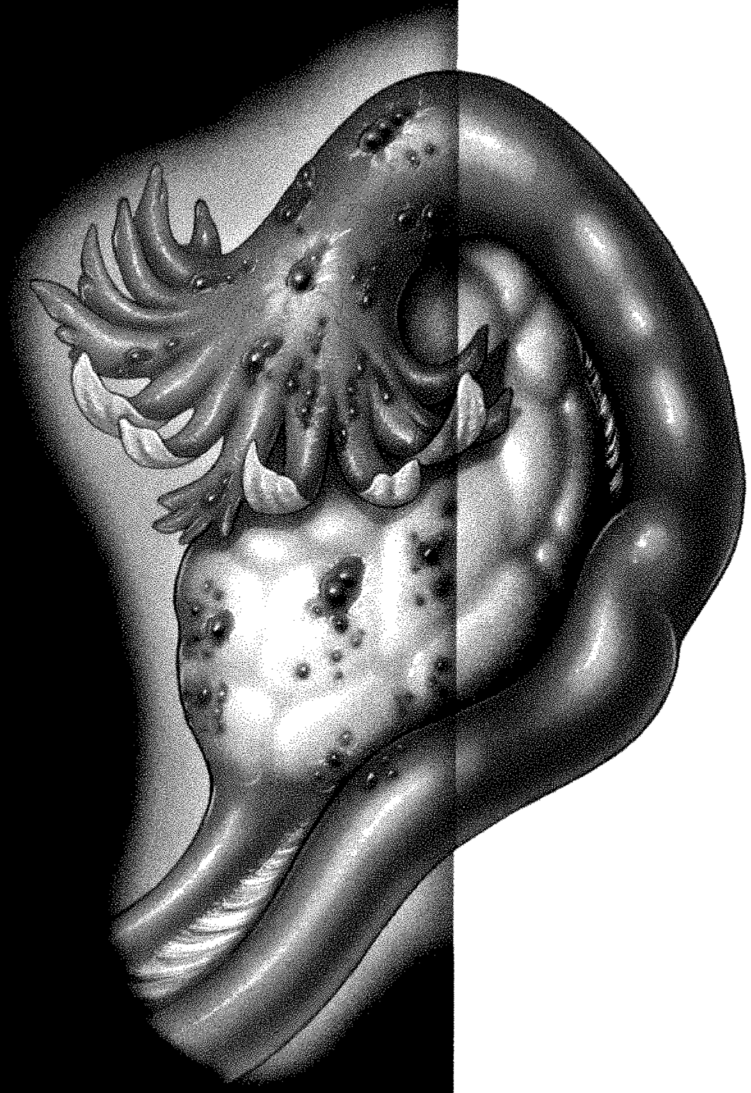
Partnership for a Drug-Free Ameri

IN THE MANAGEMENT
OF ENDOMETRIOSIS

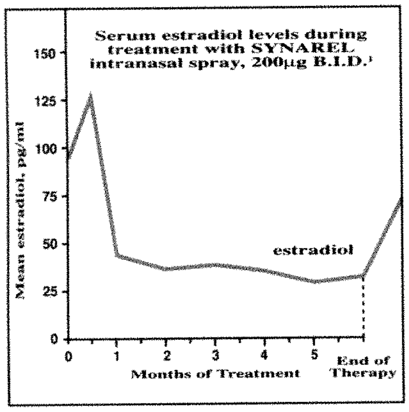


enough is enough

Insufficient estradiol suppression may not resolve the symptoms of endometriosis. Excessive suppression may create additional problems for your patients.
SYNAREL intranasal spray promises no less than you need – and no more than you want.

Power to suppress estradiol to levels that result in effective relief

SYNAREL intranasal spray, 200μg B.I.D., lowers serum estradiol to near menopausal levels within approximately 1 month—and maintains those levels throughout the 6-month course of therapy.* As a result, 92% of patients (n=143) taking SYNAREL were symptom-free or had only mild symptoms following a 6-month course of therapy. And, of the 60% of patients (n=110) who had complete relief of symptoms, 83% remained symptom-free or experienced only mild symptoms 6 months after treatment with SYNAREL was discontinued. Retreatment cannot be recommended since safety data for retreatment are not currently available.



Control in the management of hypoestrogenic and therapeutic effects

SYNAREL produces minimal impact on bone, as well as a predictable and manageable hypoestrogenic profile. What's more, SYNAREL lets you terminate treatment immediately should that be required for any reason—unlike the depot form of GnRH† therapy. In fact, drug clearance with SYNAREL usually occurs within 24 hours.[2]

Bone density changes during and after treatment with SYNAREL intranasal spray, 400 μg/day [Percent changes from baseline]

Site Method Units	Time of Study Baseline	End of Treatment	Post-treatment
Lumbar Vertebrae QCT* Integral (g/vertebrae) n=21	13.4	12.8 –4.3%	13.1 –3.3%
Trabecular Bone of Vertebrae QCT* (mg/cc) n=23	161.3	147.6 –8.7%	152.0 –4.9%
Lumbar Vertebrae DPA† (g/cm²) n=6	0.98	0.93 –5.9%	0.96 –1.4%
Distal Radius SPA‡ (Units) n=6	40.2	39.5 –1.6%	39.6 –0.8%

*Quantitative computed tomography ‡Single photon absorptiometry
†Dual photon absorptiometry

SYNAREL is also well tolerated, with a low incidence of nasal irritation (10%). And, since SYNAREL lowers estrogen without adding androgens, it helps you avoid potentially irreversible androgenic effects. (The most frequent side effects are those associated with hypoestrogenism.)

In the management of endometriosis, only SYNAREL can balance the power you need with the control you want in a unique intranasal spray. For more information, please call 1-800-727-0400.

*Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.
†Gonadotropin-releasing hormone analog.

SYNTEX
SYNTEX LABORATORIES, INC
PALO ALTO, CA 94304
Committed to the OB/GYN and women's healthcare

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.
INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.
CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.
WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.
When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.
PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve spontaneously or may require drug discontinuation or surgery.
Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the dose. Counsel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients. 3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician. 4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content. 6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption. 7. Retreatment cannot be recommended since safety data beyond 6 months are not available.
Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.
Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.
Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.
Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.
Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.
Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.
Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.
Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (± SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.
Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.
OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

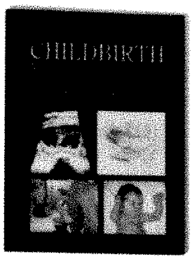
YOUR PATIENTS COUNT ON YOU FOR ANSWERS...

Here are two "must-have" resources to help you explain the mysteries of childbirth to your patients. Using dramatic full-color photos and ultrasound scans, these atlases provide step-by-step coverage of fetal development and childbirth.



New!

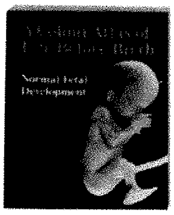
A COLOR ATLAS OF CHILDBIRTH AND OBSTETRIC TECHNIQUES
Farook Al-Azzawi, MBChB, MA, PhD, MRCOG

- Includes coverage of breech delivery, management of twins, operative vaginal delivery and the three most common types of caesarean births.
- Full color photographs depict all aspects of childbirth, with line drawings used to explain movement of the baby.
- Covers prenatal care and management of labor.

1991. 144 pages, 341 ills. A Wolfe Medical Publishers, Ltd. title. (Book Code: 06287)

New!

COLOR ATLAS OF LIFE BEFORE BIRTH: Normal Fetal Development
Marjorie A. England



- Section I covers overall development of the embryo and fetus and their relationship to the placenta, amnion and chorionic sac.
- Section II provides extensive details on the development of individual organ systems.

1990. 216 pages, 716 ills. with 710 in color. A Wolfe Medical Publishers, Ltd. title. (Book Code: 20326)

FLR-714-031-03

Transcervical endoscopic verification of congenital anomalies in the second trimester of pregnancy

Mark T. Cullen, MD,[a] John Whetham, MD,[b] Richard R. Viscarello, MD,[b]
E. Albert Reece, MD,[b] Luis Sanchez-Ramos, MD,[a] and John C. Hobbins, MD[b]
Jacksonville, Florida, and New Haven, Connecticut

Transcervical endoscopy was used to confirm prenatally diagnosed anomalies before elective termination of pregnancy. A complete anatomic survey was accomplished in 10 (70%) of 14 cases studied. Information was added to the ultrasonographic diagnosis in two cases, which changed the diagnosis in one fetus. (Am J Obstet Gynecol 1991;165:95-7.)

Key words: Prenatal diagnosis, endoscopy, genetic counseling

The widespread use of diagnostic ultrasonography in the prenatal diagnosis of structural anomalies allows the option of pregnancy interruption. It is imperative to confirm these suspicions and to evaluate the fetus for subtle defects so that accurate patient counseling can be offered regarding future pregnancies. Whereas a discrete isolated structural defect probably would not be missed, the addition of multiple defects might suggest a genetic syndrome with a higher recurrence rate.

Dilatation and evacuation and prostaglandin induction are commonly used for termination in the second trimester of pregnancy and often render the specimen unsatisfactory for pathologic examination.

In this study we evaluated the utility of transcervical endoscopy in the second trimester to visualize the fetus before the termination of pregnancy in an attempt to confirm prenatally suspected congenital anomalies.

Methods and material

Fourteen patients underwent endoscopic procedures before termination of pregnancy at either The University of Florida Health Science Center at Jacksonville or Yale–New Haven Hospital. Indications for termination included suspicion of a congenital anomaly on ultrasonography (nine patients), aneuploidy detected by amniocentesis (two patients), and three elective terminations. Gestational ages ranged from 14 to 19 menstrual weeks.

Informed consent was obtained under a protocol by the Human Investigation Committee. The endoscopic technique used was similar to that previously reported.[1] Rigid endoscopes (Karl Storz, Culver City, Calif.) 30 cm in length with diameters ranging from 2 to 3.5 mm

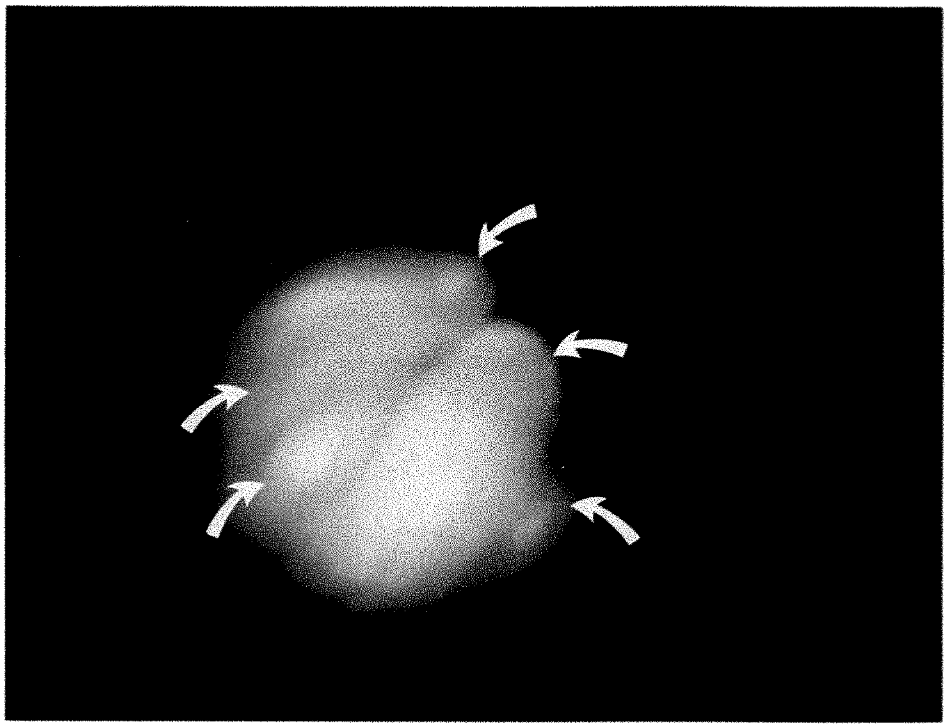

Fig. 1. Endoscopic picture of clinodactyly of hand in fetus at 19 weeks' gestation with multiple pterygium and cystic hygroma. *Arrows* indicate fingers.

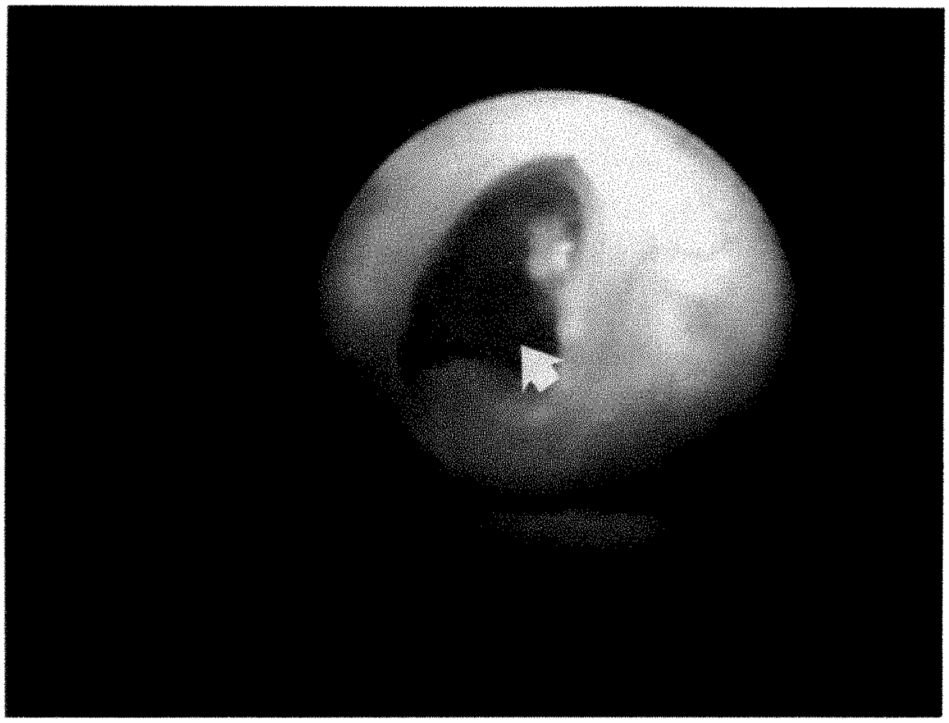

Fig. 2. Endoscopic picture of fetus at 18 weeks' gestation with an encephalocele and cleft palate *(arrow)*. Defect was viewed through endoscope, which was inserted into oral cavity and occupies most of picture.

were introduced through the cervix into the uterine cavity under ultrasonographic guidance. An attempt was made to rupture the opaque chorion while leaving the amnion intact.

Procedures were performed by one of the two operators (M.T.C. or J.W.), and they were viewed via a mini video camera and recorded for subsequent review.

Anesthesia was not induced in the cases in which prostaglandin was used. In cases in which dilatation and evacuation were performed, general anesthesia was often used for the termination. While it is not necessary to dilate the cervix for the endoscopic procedure, laminaria were often placed for the abortion.

A complete anatomic survey of the fetus was attempted; this included visualization of the dorsal and ventral walls, extremities, genitalia, and head and neck, including the oral pharynx. A procedure was considered complete if all but the oral pharynx could be visualized and incomplete if any of the previously mentioned sites were not visualized.

Results

Table I lists the indications for termination of pregnancy, anomalies suspected by ultrasonography, and the results of the endoscopic procedure.

No maternal morbidity or discomfort was reported. Five patients had pregnancy termination by prostaglandin induction and nine by dilatation and evacuation.

Rupture of membranes occurred in all but three cases. While it was our intent to avoid this, it did not detract from the ability to view the fetus in all but one procedure. There was one case in which a partial placenta previa was traversed, which led to a bloody field of view and limited visualization.

The anatomic survey was thought to be complete in 10 cases, helpful but incomplete in three, and inadequate in one. The mouth and oral pharynx could be seen in only three cases. Reasons for the incomplete or difficult examination included breech presentation, rapid leak of amniotic fluid, and a bloody field. The anomalies suspected by ultrasonography were verified in all cases.

In two cases additional information was found at the time of endoscopy; in one of these, the endoscopic findings changed the final diagnosis. One fetus with cystic hygroma had multiple pterygium (Fig. 1), micropenis, and a cleft palate. A cleft palate (Fig. 2) was identified in a fetus with prenatal diagnosis of an encephalocele made by inserting the endoscope into the oral cavity of the fetus.

Comment

Prenatal diagnosis of congenital anomalies is possible in the first[2] and early second[3] trimesters. As ultrasonographic equipment and expertise become readily available, more fetuses will be scanned, and more defects will be detected.

While the prenatal identification of the anomalies is important, accurate genetic consultation with regard to future pregnancies is contingent on complete and verified prenatal data. Although endoscopic visualization does not allow insight into the internal anatomy of the fetus, it does permit an extensive review of the external anatomy. This information was imperative in counseling the third patient in Table I, who was faced with a potential autosomal recessive inheritance in a fetus with a lethal form of multiple pterigium[4] instead of the low recurrence rate for a fetus with isolated cystic hygroma.

Potential difficulties with the procedure include the inability to obtain a complete anatomic survey, rupture of the membranes, and bleeding. While rupture of the membranes occurred often, fluid leakage was often slow and did not detract from the examination. In one case a placenta previa was traversed and bled, which led to poor visualization. Placenta previa might limit the utility of this procedure. We feel that the quality of the examination can be optimized and that risks, such as uterine perforation, can be minimized by ultrasonographic guidance and operator experience.

Transcervical endoscopy differs from transcervical embryoscopy[1] in two ways. The larger size of the fetus in advanced gestation does not allow it to be seen in toto; instead it must be viewed in small segments as it is during fetoscopy. Also, at 13 weeks' gestation the amnion and chorion have often fused, so that it is difficult, if not impossible, to prevent rupture of the membranes. This can be minimized by performing transcervical endoscopy at the earliest possible gestational age and by introducing the scope at an angle more acute than perpendicular to the membranes. The high incidence of ruptured membranes currently precludes use of this technique in continuing pregnancies. Unlike fetoscopy, endoscopy uses a transcervical approach with a larger-diameter scope equipped with a wide-angle lens; the procedure requires no anesthesia and permits a larger field of view.

Transcervical endoscopy can be useful in the verification of suspected structural anomalies before elective termination of pregnancy.

Trophoblast from anembryonic pregnancy has both a maternal and a paternal contribution to its genome

Deborah J. Henderson, BSc,[a] Phillip R. Bennett, MD,[a] Charles H. Rodeck,[a]
Gillian S. Gau, MD,[b] Susan Blunt, MSc,[c] and Gudrun E. Moore, PhD[a]
London, England

In a series of 14 anembryonic pregnancies, deoxyribonucleic acid from trophoblast was examined with locus-specific minisatellite probes. It was found in each case that trophoblast from anembryonic pregnancy has both a maternal and a paternal contribution to its genome. This means that although anembryonic pregnancy shares characteristics with complete hydatidiform mole and androgenetic development in the mouse in that there is no embryo, it does not arise by the same genetic process. Of three anembryonic pregnancies that were successfully karyotyped, two had normal female 46,XX chromosome constitutions and one had an abnormal 47,XX + 16 complement. The sex of the trophoblast in each anembryonic pregnancy was determined with a deoxyribonucleic acid probe with Y-specific bands. A male-to-female ratio of 6:8 was found, which is not significantly different from normal. (AM J OBSTET GYNECOL 1991;165:98-102.)

Key words: Anembryonic pregnancy, locus-specific minisatellite deoxyribonucleic acid probes, hydatidiform mole

Anembryonic pregnancy or blighted ovum is a condition in which there is no embryo proper but there is apparently normal development of the extraembryonic tissues. As many as 16% of all clinically recognized pregnancies may be anembryonic.[1] These pregnancies are usually first seen clinically between 8 and 14 weeks' gestation as incomplete or missed abortions but are now commonly identified by ultrasonographic imaging in early pregnancy. Abnormal sonar features include loss of definition of the gestational sac, a gestational sac that is small for dates, failure of growth of the sac, and absence of both fetal echoes and fetal heart activity. A final diagnosis of anembryonic pregnancy is made when no fetal echoes can be seen and when consequent examination of the retained products of conception reveals no fetal parts.

Very little is known about anembryonic pregnancy and its causes. It may be that the embryo fails to develop beyond a very early stage, or that it develops normally for some time and is subsequently shed, leaving the remaining trophoblast viable. Anembryonic development is common in extrauterine pregnancies with rates of 40% and higher quoted in the literature.[2] Several authors consider there to be a relationship between the length of time of intratubal residence and the development of anembryonic pregnancy.[3, 4] In extrauterine pregnancies it has been suggested that anembryonic development arises predominantly as a result of exogenous influences.[5] Why development of anembryonic pregnancy is more common in extrauterine pregnancy, and whether this bears any relationship to intrauterine anembryonic pregnancy is unknown.

Studies in the mouse have revealed that the developing conceptus needs both a maternal and paternal contribution to its genome. Mouse androgenones are produced by removal of the maternal pronucleus from a zygote and its replacement with another male pronucleus. These androgenones often fail to implant. Those that do implant have developmentally retarded embryos, although the trophoblast develops relatively normally.[6] Gynogenones are produced by adding a female pronucleus to a haploid parthenogenetic egg. These generally develop poorly after implantation, although in some cases a small but apparently normal embryo is produced. However, in these cases the extraembryonic tissues are poorly developed.[7] Therefore the maternal genome appears to be largely responsible for the development of the embryo, with the paternal genome being largely responsible for the development of the extraembryonic tissues. Androgenetic development resembles anembryonic pregnancy, with relatively normal development of the extraembryonic tissues but little or no development of the embryo proper.

In human beings, complete hydatidiform mole is a type of anembryonic pregnancy. In complete mole

there is no development of the embryo proper but there is abnormal development of the extraembryonic tissues. Complete hydatidiform mole usually has a 46,XX chromosome constitution, all of which are paternally derived.[8] The most common mechanism by which complete hydatidiform mole arises is fertilization of an anucleate ovum by a haploid sperm that then divides to give the 46,XX chromosome constitution.[8] Histologically some similarities exist between trophoblast from anembryonic pregnancy and complete hydatidiform mole including enlarged villi, cytotrophoblast proliferation, and localized molar degeneration of villi. In exceptional cases avascular chorionic villi may be seen in trophoblast from anembryonic pregnancy.[2]

In view of the similarities between human anembryonic pregnancy, complete hydatidiform mole, and mouse androgenone development, we have performed experiments to determine the parental origin of the trophoblast from anembryonic pregnancy with the use of single locus-specific minisatellite deoxyribonucleic acid (DNA) probes.

Material and methods

In this study a clinical diagnosis of anembryonic pregnancy was made when no embryo proper could be identified within a gestation sac of >4 ml at two examinations separated by at least 1 week. A total of 19 anembryonic pregnancies were identified by ultrasonography at Queen Charlotte's and Chelsea Hospital and Hammersmith Hospital, London. Approval for the study was obtained from the local ethical committee. Products of conception were obtained as soon as possible after evacuation of the uterus. A small piece of trophoblast tissue was stored at 4° C in sterile saline solution and then cultured for chromosomal studies, the rest was frozen at −70° C. A blood sample was collected from each parent into ethylenediaminetetraacetic acid tubes and stored at −70° C. DNA was made from the tissues and blood with standard techniques. DNA (4 μg) was digested for 6 hours at 37° C with the restriction enzyme *Hin*fI. The fragments were separated in a 0.8% agarose gel by electrophoresis. Southern blotting was used to transfer DNA to Hybond-N nylon filters (Amersham International, United Kingdom). Filters were prehybridized overnight at 65° C in 10 × Denhardt's solution, 6 × standard saline citrate (20 × standard saline citrate is 3 mol/L sodium chloride, 0.3 mol/L sodium citrate), 0.5% sodium dodecylsulfate, 0.005 mol/L ethylenediaminetetraacetic acid pH 8, 2% sodium pyrophosphate, and 0.1 mg/ml denatured salmon sperm and then hybridized overnight in the same solution with 10% dextran sulfate, 200 μg/ml sheared single-stranded human placental competitor DNA, and 10 ng of the locus-specific probe pλg3.[9] The probe was labeled with phosphorous 32 deoxycytidine triphosphate by random hexanucleotide priming.[10] Filters were washed to a stringency of 0.1 × standard saline citrate at 65° C and then exposed to x-ray film for 3 days at −70° C in the presence of an intensifying screen.

The probe was subsequently stripped from the filter by washing in 0.1 mol/L sodium hydroxide for 20 minutes followed by washing in 0.5 mol/L Tris hydrochloride base with 3 mol/L sodium chloride, pH 7.5 for 10 minutes at room temperature. Further hybridization was carried out with the locus-specific probes λMS31 and λMS43.[11] Probes pλg3 and λMS31 are located on chromosome 7, with λMS43 located on chromosome 12.[12] All three probes have a heterozygosity within the general population of above 93%.[11]

A variable number of tandem repeats probe from the X chromosome, S232, which has homology to the Y chromosome and therefore has Y-specific bands,[12] was used to probe *Taq* I–digested DNA from both the parents, and trophoblast from the anembryonic pregnancy. From these autoradiographs the sex of the trophoblast from each anembryonic pregnancy could be established.

Sections were taken from each trophoblast sample, stained with hemotoxylin and eosin, and examined for maternal tissue contamination.

Results

Of the 19 anembryonic pregnancies, histologic examination showed contamination by maternal decidua in five; these instances were excluded from further study. In no case did histologic examination identify fetal parts.

With use of the locus-specific minisatellite probes all 14 of the trophoblast samples from anembryonic pregnancies were shown to have both a maternal and a paternal genetic contribution to their genome. Both a maternal and a paternal band could be seen in each (Fig. 1). In one case four *Hin*fI restriction fragments were seen in the trophoblast lanes with the probe pλg3, two being derived from each parent. However, with the locus-specific probes λMS31 and λMS43 only three bands could be seen.

With the X-chromosome probe S232, which has Y-specific bands, it was found that the female-to-male sex ratio for the trophoblast from anembryonic pregnancy was 8:6, which is not significantly different from normal.

Karyotyping was successful in only three cases. Of these, two cases had a normal 46,XX chromosome complement and one was abnormal, 47,XX + 16. Karyotyping was frequently unsuccessful because of failure of the cultures to grow or infection of the cultures.

Comment

It is apparent from this study that trophoblast in anembryonic pregnancy does not arise by the same ge-

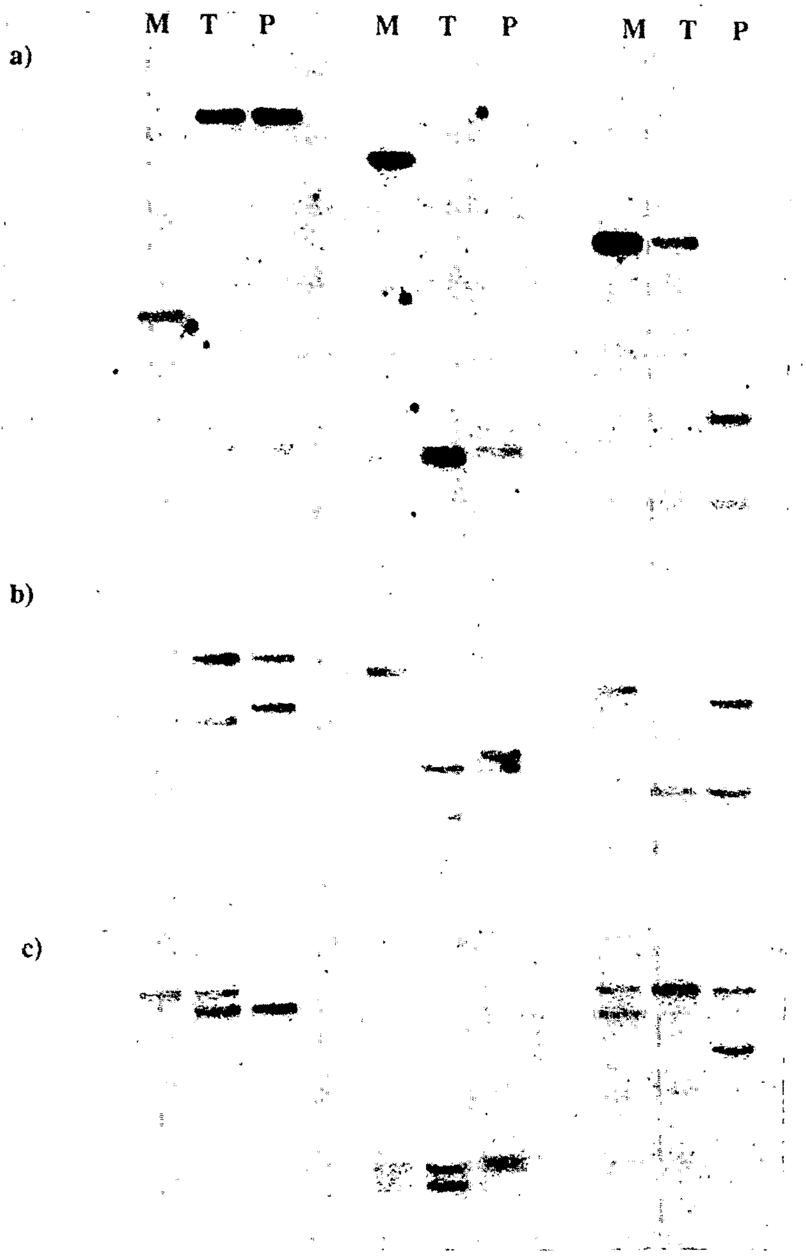

Fig. 1. Autoradiographs of three data sets of DNA from maternal blood *(M)*, trophoblast from anembryonic pregnancy *(T)*, and paternal blood *(P)* probed with three locus-specific minisatellite probes **a**, λpg3; **b**, λMS31; and **c**, λMS43.

netic mechanism as does complete hydatidiform mole, inasmuch as the tissue has both a maternal and a paternal contribution to its genome. This also suggests that anembryonic pregnancy is not equivalent to the generation of androgenones in the mouse, which have extraembryonic tissues at the implantation site but little or no development of the embryo proper. In the case in which four bands were seen in the trophoblast lane with the probe pλg3, it is likely that the tissue resulted from a twin pregnancy. With the probes λMS31 and λMS43 three bands were seen in the trophoblast lane, one band presumably being shared by the twin trophoblasts. Because there was no sharing of alleles by the parents, tetraploidy would be expected to produce four bands with each probe. Previous studies have suggested that up to 60% of anembryonic pregnancies show some chromosomal abnormality (Davidson HR, Duncan Guthrie Institute, Glasgow. Unpublished results). Our data so far have revealed one trisomy 16 karyotype, which is the most common trisomy found in tissues from spontaneous abortions.[14] Both of the other karyotypes obtained showed apparently normal female 46,XX chromosome constitutions. We have been unable to exclude the possibility that there are gross chromosomal abnormalities within the tissue. Triploidy, tetraploidy, and trisomies of various chromosomes have been reported in anembryonic trophoblast (Davidson HR. Unpublished results). Trophoblast from anembryonic pregnancy appears to be very susceptible to infection on culture. This could be because the tissue in the uterus is often necrotic at the time of evacuation of the uterus, decreasing viability with increased risk of infection. Alternatively the tissue may become infected while passing through the vagina. These problems could be solved by use of direct karyotyping (with no culture step), although this relies on there being cells in the metaphase stage of mitosis at the time of evacuation of the uterus. It would appear that there is no sex bias in the trophoblast from anembryonic pregnancy.

Several other mechanisms can be postulated that could result in anembryonic pregnancy. Uniparental disomy, a phenomenon whereby both of any one pair of homologous chromosomes are from the same parent, is one possible mechanism. Uniparental disomies have been reported in cases of cystic fibrosis in which only one parent was a cystic fibrosis carrier. On closer examination it became apparent that both chromosome 7s had been inherited from the one carrier parent.[15, 16] It is possible that uniparental disomies of other chromosomes might be lethal to the developing conceptus, but may allow the development of anembryonic pregnancy. Such a hypothesis can be tested with DNA probes for each chromosome in turn. Inasmuch as probes pλg3, λMS31, and λMS43 are located on chromosomes 7 and 12, we know that chromosomes 7 and 12 are not uniparentally disomic in any of our experimental samples.

In view of the similarity of our findings for trophoblast from anembryonic pregnancy and normal conceptions, it may be that anembryonic pregnancy starts normally but for some reason discards the amnion and embryo, retaining the chorion. Missed abortions are often seen with an underdeveloped embryo small for gestational age, and it is possible that this embryo is simply discarded in anembryonic pregnancy.[17]

Incorrect genomic imprinting might result in inappropriate developmental gene expression, which in turn may lead to a nonviable conceptus. Chromosomes appear to be imprinted in such a way that particular regions of DNA are expressed according to their parental chromosome origin.[18] At different developmental stages particular genes are expressed from one parent rather than from the other. Genomic imprinting is thought to be achieved by methylation of DNA at selected CpG sites upstream from the first exons of the gene. It could be that in anembryonic pregnancy, genes necessary for the development of the embryo are incorrectly imprinted and thus fail to be expressed in the developing conceptus. This could be studied by examination of the methylation status of various genes known to be important in development, in comparison with normal trophoblast.

It may be that there are differences in the level or site of genes known to be important in development, such as proto-oncogenes and growth factors, between anembryonic and normal trophoblast. It has been shown that several proto-oncogenes are expressed in a stage-specific and tissue-specific manner in the human placenta[19] and these could be examined within normal trophoblast and trophoblast from anembryonic pregnancy.

It would seem that with respect to parental origin, the trophoblast from anembryonic pregnancy is normal. This is of interest in the light of studies that involve androgenetic development in the mouse and of complete hydatidiform mole in human beings, which share similar characteristics. Further studies in the areas outlined in this article are being carried out in this laboratory and may help to determine the causes of anembryonic pregnancy.

We thank Cellmark Diagnostics for providing the locus-specific minisatellite probes λg3, λMS31, and λMS43. In addition we thank Dr. Pauline Yen for the donation of the probe S232.

Hydrops fetalis in the McKusick-Kaufman syndrome: A case report

Robin S. Rosen, MD, and Maureen E. Bocian, MD
Orange, California

McKusick-Kaufman syndrome is an autosomal recessive multiple malformation syndrome characterized by hydrometrocolpos and polydactyly. We report on a patient with McKusick-Kaufman syndrome and severe hydrops. This case illustrates the necessity of genetic evaluations for all patients with unexplained hydrops. (AM J OBSTET GYNECOL 1991;165:102-3.)

Key words: McKusick-Kaufman syndrome, nonimmune hydrops, hydrometrocolpos

Genetic causes of nonimmune hydrops are numerous but frequently are undiagnosed. We present the first report of which we are aware of McKusick-Kaufman syndrome, an autosomal recessive disorder, and classic nonimmune hydrops. Consider genetic disease in all cases of unexplained hydrops.

Case report

A 24-year-old gravida 2, para 1 woman was referred at 30-4/7 weeks' gestation. Ultrasonography revealed mild polyhydramnios, bilateral hydronephrosis, multicystic kidneys, abnormal bladder, and fetal hydrops with marked ascites. Her blood type was A positive; rapid plasma reagin test results were nonreactive. Amniocentesis and cordocentesis revealed a normal 46,XX fetal karyotype, negative Coombs test results, hematocrit 40.5%, albumin 1.9 gm/dl, total protein 3.4 gm/dl, normal immunoglobulin M, and a lecithin/sphingomyelin ratio of 1.6. On hospital day 8 emergency cesarean section was performed because of maternal fever and worsening hydrops.

A 2710 gm edematous female with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively, and with postaxial polydactyly on three extremities was delivered. Urinalysis, serum glutamate oxaloacetate transaminase, serum glutamate pyruvate transaminase, blood urea nitrogen, and creatinine values were normal. Venous hematocrit was 38.2%, albumin 2.0 gm/dl, and total protein 3.2 gm/dl. The placenta was normal. A patent ductus arteriosus was surgically ligated after two courses of indomethacin (Indocin) failed. No other cardiac abnormality was found. By the time of the patient's discharge, serum albumin had increased to 4.5 gm/dl and total protein to 6.2 gm/dl.

A blind vaginal orifice was discovered in normal appearing external genitalia, suggesting a diagnosis of McKusick-Kaufman syndrome. Radiographic studies confirmed the presence of bilateral hydroureters, a dilated, fluid-filled uterus, and a normal bladder; no renal cysts were seen. Cystoscopy revealed a common genitourinary sinus with a vesicovaginal fistula. After

vaginostomy and drainage, the blood urea nitrogen and creatinine values, which had risen to 26 mg/dl and 1.9 mg/dl, respectively, declined to 13 mg/dl and 0.5 mg/dl by 31 days. After discharge she had persistent ureteropelvic junction obstruction and subsequently underwent exploration and pyeloplasty on the left kidney for an aberrant lower pole vessel. However, obstruction and electrolyte imbalances recurred. At approximately 1 year of age she was lost to follow-up.

Comment

Nonimmune hydrops carries a poor prognosis, perinatal mortality in most series being greater than 50%. Whereas traditional studies suggest the vast majority of cases will have no identifiable etiologic factor, a cause or predisposing condition can be found in more than 75% of cases with full genetic and pathologic evaluations.[1] Because genetic disorders can have a significant recurrence risk in future pregnancies, and because the prognosis and management for affected persons may depend greatly on the underlying disease, evaluation for a possible genetic cause is imperative for all cases of unexplained nonimmune hydrops.

Whereas there are many published cases of McKusick-Kaufman syndrome,[2] this is the first report of which we are aware of true nonimmune hydrops in a fetus with classic McKusick-Kaufman syndrome. The hydrops was presumed to be a result of decreased serum oncotic pressure due to the hypoalbuminemia and hypoproteinemia, found both prenatally and postnatally. However, the cause of the low protein level is unknown because she had normal liver and renal function at birth. This patient also shows that in cases of hydrops, polyhydramnios can coexist with urinary tract obstruction when the obstruction is either partial or intermittent.

Hydrometrocolpos has been diagnosed antenatally in cases in which there is a large mass that extends into the fetal abdomen. In our patient the mass was seen on every ultrasonographic examination, but was interpreted as the fetal bladder because of its small and stable size. However, it was large enough to cause intermittent ureteropelvic junction obstruction.

This patient shows several interesting features: (1) an association between McKusick-Kaufman syndrome, a rare autosomal recessive disorder, and nonimmune fetal hydrops; (2) polyhydramnios associated with urinary tract obstruction; and (3) the importance of an interdisciplinary approach for cases of nonimmune hydrops. Our patient retained good renal function in spite of fetal and early neonatal obstruction. However, if the diagnosis can be recognized prenatally in other affected persons, intervention, such as intrauterine decompression of the dilated uterus and vagina, may prevent progressive renal compromise. Being alert to subtle clues, such as a persistently full fetal bladder, may aid in prenatal diagnosis.

Correct diagnosis, both prenatally and postnatally, of potentially treatable and recurrent causes of nonimmune fetal hydrops is critical for providing appropriate perinatal management and therapy and for accurate genetic counseling.

Correlation between sexual abuse and somatization in women with somatic and nonsomatic chronic pelvic pain

Robert C. Reiter, MD,[a] Lisa R. Shakerin, MD,[a] Joseph C. Gambone, DO,[b] and Alison K. Milburn, PhD[a]

Iowa City, Iowa, and Los Angeles, California

After a comprehensive clinical and psychological evaluation, 99 women with pelvic pain of at least 6 months' duration and normal findings at laparoscopy were divided into two groups, including 47 women with probable somatic causes of pain (group 1) and 52 women without identifiable somatic abnormality (group 2). Women without identifiable somatic abnormality (group 2) were younger, had higher mean somatization scores, and reported an earlier mean age at first intercourse, a higher number of total sexual partners, and a higher prevalence of sexual abuse before the age of 20. Within group 2 (nonsomatic pain) but not within group 1, mean somatization scores were significantly higher among women with a history of sexual abuse than among women with a negative history. When analyzed as risks for nonsomatic pelvic pain, the positive predictive value of both a history of sexual abuse and a high somatization score was 78% (relative risk compared with that of women with zero or one risk factor, 2.1; $p < 0.0001$). These data suggest that the psychosocial profile of women with nonsomatic pelvic pain differs from that of women with somatic pelvic pain and that previous sexual abuse is a significant predisposing risk for somatization and non-somatic chronic pelvic pain. (AM J OBSTET GYNECOL 1991;165:104-9.)

Key words: Hysterectomy, pain, sexual abuse, somatization

Chronic pelvic pain, defined as noncyclic pelvic pain of >6 months' duration, is a common gynecologic complaint, accounting for 10% of outpatient gynecologic consultations and indicating up to 25% of diagnostic laparoscopies.[1] More important, chronic pain is listed as the indication for 10% to 19% of hysterectomies in the United States; thus it is the third most frequent indication (after leiomyomas and abnormal bleeding) and accounts for approximately 78,000 hysterectomies annually.[2-4]

Studies comparing women with chronic pelvic pain to pain-free control subjects have demonstrated significant differences in rates of sexual dysfunction, depression, somatization, and abnormal psychological testing between pain patients and controls.[1, 5-8] By contrast, studies comparing the psychosocial profiles of women with presumedly somatic chronic pelvic pain (such as women with endometriosis) with those of women with nonsomatic chronic pelvic pain have not demonstrated any significant differences in these variables between groups.[6-10] An exception to this was the study of Magni et al.,[8] which documented a higher self-rating of depression in women with chronic pain and normal laparoscopic findings as compared with those with abnormal laparoscopic findings. These findings appear to suggest that chronic pain (somatic or otherwise) is the cause, rather than the effect, of the associated psychopathologic condition.

Unfortunately, these latter studies suffer from a consistent methodologic constraint, which is reliance on laparoscopy to discriminate "somatic pain" controls from "nonsomatic" pain study populations.[6-10] Several recent investigations have documented that laparoscopically invisible nongynecologic somatic abnormalities, such as irritable bowel syndrome, abdominal wall neural "trigger points," and chronic urethritis, may constitute many cases of pelvic pain with normal laparoscopic results.[11-13] Furthermore, two recent studies reported that the prevalence of classic, laparoscopically visible somatic intrapelvic findings, such as endometriosis and pelvic adhesions, was the same in patients undergoing laparoscopy because of pain and in pain-free patients undergoing laparoscopy because of infertility or tubal sterilization.[5, 14, 15] Together, these investigations fundamentally challenge both the sensitivity and the specificity of laparoscopy for the diagnosis of pelvic pain and the validity of the conclusions reported from trials that used this method.

High somatization (somatic symptoms) scores and preoccupation with physical symptoms and concerns

have been observed in adult women with histories of sexual and nonsexual physical abuse.[16-18] Several groups, including ours, have reported higher rates of both somatization and childhood sexual trauma in women with chronic pelvic pain as compared with pain-free control subjects.[1, 5] However, the correlation between these variables within a population of women with chronic pelvic pain (or subsets of women with somatic or nonsomatic chronic pelvic pain) has not been reported.

The purpose of this study was twofold. First, we wished to compare the demographic and psychosocial profiles of groups of women with somatic and nonsomatic pelvic pain by means of diagnostic methods other than laparoscopy to distinguish groups. Second, we wished to correlate history of sexual trauma and somatization in groups of women with chronic pelvic pain with and without identifiable somatic pathology.

Material and methods

Between June 1986 and January 1989, 135 women were referred to a multidisciplinary pelvic pain clinic at San Diego Naval Hospital. Ninety-nine women who completed a comprehensive medical and psychological evaluation comprise the study population. The demographic profile of this population has been reported previously.[1] All of these women had complained of pelvic pain of at least 6 months' duration and had undergone a baseline workup consisting of history and physical examination, laboratory evaluation, and laparoscopy, the results of which were considered normal by the referring physician. The study was reviewed and approved by our institutional review board.

All patients completed a comprehensive medical and historical questionnaire conducted by private structured interview with a female gynecology nurse practitioner. In addition to standard medical and pain information, all subjects completed a detailed sexual history, including age at first coitus, current and total numbers of sexual partners, and history of previous major psychosexual trauma, defined as incest (coitus with a legal relative), repetitive sexual molestation (noncoital genital touching or exposure with or without vaginal, oral, or anal penetration), or rape before the age of 20. Isolated instances of molestation were not included in this definition for purposes of tabulation. The medical questionnaire included a standard screening protocol for irritable bowel syndrome, as described elsewhere.[11]

A somatization scale, which has been previously reported,[1] consisting of 26 common somatic and emotional symptoms unrelated to pelvic or abdominal pain was administered to all subjects (Table I). A net somatization score was determined for each patient on the basis of the total number of items endorsed as sufficient to require medical consulation or to interfere with usual daily activities. For purposes of calculating predictive values for nonsomatic pelvic pain, somatization scores of 0 to 7 were arbitrarily defined as "low" and scores from 8 to 26 were defined as "high."

(From Reiter RC, and Gambone JC. Demographic and historical variables in women with idiopathic chronic pelvic pain. Obstet Gynecol 1990;75:428. By permission of the American College of Obstetricians and Gynecologists.)

The standardized medical evaluation and diagnostic criteria for somatic diagnoses used in the clinic have been reported previously.[13] Briefly, all patients underwent a repeat physical examination, which included specific attempts to elicit trigonal or urethral tenderness or abdominal wall myofascial pain or "trigger points" as described by Slocumb,[12] Thompson and Francis,[19] and Applegate.[20] Screening laboratory tests included complete blood count, stool guaiac test, urinalysis and urine culture, cervical culture, cytologic testing, and chlamydial antigen testing. Additional special studies, such as bowel radiographs, urethrocystoscopy, intravenous pyelography, and abdominal trigger point injections, were obtained as indicated.

On the basis of the presence or absence of identifiable somatic abnormality, patients were divided into two groups. Group 1 consisted of 47 women with probable somatic pelvic pain and group 2 consisted of 52 women without identifiable somatic abnormality. The diagnostic profiles of patients in group 1 are summarized in Table II. All statistical comparisons were done with the χ^2 or Student t test as appropriate.

Results

Group comparisons for variables of interest are summarized in Table III. The mean ages of 47 women with somatic pelvic pain (30.0 ± 7.7 years) were significantly older than those of 52 women with nonsomatic pain (27.3 ± 6.0 years), although the duration of pain was

similar for both groups. No significant differences in cumulative gravidity or parity, racial distribution, educational attainment, marital status, or cumulative operations or current medications were observed between the two groups. However, women with nonsomatic pelvic pain reported a younger age at first intercourse (15.2 ± 3.2 vs 17.9 ± 3.0 years), a higher number of total sexual partners (6.7 ± 6.2 vs 4.6 ± 5.0), and a substantially higher prevalence of sexual abuse before the age of 20 (67% vs 28%), as compared with women with somatic diagnoses.

Somatization scores in both groups stratified by history of sexual trauma are summarized in Table IV. A strong correlation was observed between somatization score and a history of sexual trauma in group 2 (nonsomatic pain), with a mean somatization score that was nearly twice as large for women reporting a history of sexual trauma (10.3 ± 4.8 vs 5.9 ± 2.9). However, no similar correlation was observed in group 1 (somatic pelvic pain).

To calculate the predictive value of history of sexual abuse and high somatization score for nonsomatic pelvic pain, cases were identified in which both of these variables were present. In the entire study population there were 37 patients who were considered to have a "high-risk" profile, defined as both a history of sexual abuse and "high" somatization scores (≥ 8). Somatic diagnoses were rendered in only eight (22%) of these women, yielding a positive predictive value of both risk factors for nonsomatic pelvic pain of 78%. Conversely, there were 62 subjects who were considered to have a "low-risk" profile (zero or one risk), defined as either a history of sexual abuse or a high somatization score (≥ 8) or neither of these. Somatic diagnoses were established in 39 of these women, yielding a negative predictive value for zero or one risk factor for nonsomatic pelvic pain of 63% ($p < 0.0001$) (cumulative relative risk for nonsomatic pelvic pain for women with both risks as compared with women with zero or one risk factor, 2.1).

Comment

Chronic pelvic pain, the third most common indication for hysterectomy, which is the second most frequent major surgical procedure in the United States, is a significant health concern of women. Histologic abnormality (usually an incidental leiomyoma) was discovered in fewer than half (41%) of the hysterectomy specimens in cases of chronic pain analyzed in a large collaborative review from the United States.[4] This symptom may indicate the presence of gynecologic disease, such as recurrent salpingitis; nongynecologic somatic abnormalities, such as abdominal trigger points; or nonsomatic (psychological) pathology, such as somatization disorder. Although the majority of these patients present to gynecologists for evaluation and treatment, the majority do not have gynecologic pathology.

Traditionally, the gold standard of gynecologic evaluation of chronic pelvic pain has been laparoscopy. A common tendency has been to assume that any visible intrapelvic abnormality, such as endometriosis or pelvic adhesions, is causally associated with the pain and that causes have been excluded if the laparoscopic findings are normal. However, there are no objective data to support these assumptions, and a substantial body of controlled investigation suggests that they are invalid.

Rapkin[14] has recently investigated the association between pelvic adhesions and chronic pelvic pain. In a review of 188 laparoscopies Rapkin[14] observed no difference in the prevalence of pelvic adhesions in patients with chronic pain as compared with pain-free infertile control subjects. Furthermore, she was unable to correlate the location or severity of pain with the location or severity of adhesions observed at laparoscopy. Similarly, the correlation between the observed severity of endometriosis (as determined by various classification schemes) and associated chronic pain is notoriously poor, with the majority of patients with mild, moderate, and severe disease reporting no symptoms at all.[21] Vernon et al.[22] have recently demonstrated in tissue culture that morphologically and visually "classic" (powder burn and mulberry spot) endometriotic implants represent inert hemosiderin "tattoos" and that metabolically active (prostaglandin-producing) endometriosis is present in morphologically subtle pink or tan implants. In a recent prospective study, Walker et al.[5] observed no difference in the prevalence of endometriosis or pelvic adhesions in groups of patients with pelvic pain and pain-free control subjects who were undergoing laparoscopy for tubal sterilization or infertility.

While these investigations have questioned whether "classic" gynecologic findings, such as endometriosis and adhesions, actually cause chronic pain, other investigations have questioned the ability of laparoscopy to rule out many somatic causes of chronic pelvic pain. Slocumb[12] diagnosed abdominal wall "trigger

points" in 131 (74%) of 177 patients referred for evaluation of chronic pelvic pain. Similarly, Hogston[11] reported that symptoms consistent with irritable bowel syndrome were evident in >60% of gynecologic referrals for chronic pelvic pain. Although the high prevalences reported for these diagnoses probably reflect observer biases, these and similar studies confirm that laparoscopy is an inadequate means of ruling out many somatic causes of pelvic pain. Our experience has confirmed this impression. We recently reported the results of clinical evaluation of >200 patients referred for evaluation of pelvic pain after normal laparoscopic findings.[13] Laparoscopically occult somatic pathology was diagnosed in almost half of these patients, with gynecologic diagnoses (usually atypical dysmenorrhea) accounting for <20%.

The implications of these data for previous investigations regarding the psychological profile of women with chronic pelvic pain are profound. Studies by Walker et al.,[5] Beard et al.,[6] Renaer et al.,[7] and Magni et al.[8] documented significantly higher rates of depression, somatization, substance abuse, adult sexual dysfunction, and "neurosis" in women with chronic pelvic pain as compared with pain-free control subjects. However, such investigations inherently fail to control for the confounding variable of chronic pain (somatic, pelvic, or otherwise), which has been shown to predispose to many of these disorders.[23-26] By contrast, studies by Beard et al.,[6] Renaer et al.,[7] Rosenthal et al.[9] and Magni et al,[8, 10] which compared patients with presumed nonsomatic pain with somatic pain control subjects, demonstrated no significant differences in rates of abnormal psychological testing, somatization, or sexual dysfunction. However, without exception, these studies relied on laparoscopy to distinguish study and control populations. In view of the investigations cited above, it seems probable that some patients with undiagnosed somatic abnormalities were included in the study populations with normal laparoscopic findings and that the presumedly somatic causes of pain in the control group with abnormal laparoscopic findings (almost uniformly pelvic adhesions or endometriosis) were in fact frequently spurious.

*Incest, repetitive molestation, or rape before age 20.

In this study all patients were referred after normal laparoscopic results, thereby eliminating inclusion of spurious laparoscopic findings in either group. Furthermore, a specific and systematic attempt was made to diagnose nongynecologic somatic causes of pain with the use of recently reported criteria and methods. What emerged from this approach was a distinct psychosocial profile of patients with and without identifiable somatic pathology. Although mean duration and severity of pain were similar, women with nonsomatic pain were younger and had significantly higher mean somatization scores. The most striking population differences involved sexual history, with patients with nonsomatic pelvic pain reporting significantly younger mean ages at first intercourse, higher total numbers of sexual partners, and higher prevalence of significant, usually childhood and adolescent sexual abuse.

Childhood sexual abuse has been associated with numerous sequelae in adult women, including sexual dysfunction, promiscuity, dependency, depression, and somatization.[18, 27-32] We observed an association between somatization and history of sexual trauma in women with nonsomatic pelvic pain. Although this relationship was not observed in women with somatic pelvic pain, the mean somatization score among women with somatic diagnoses and a history of sexual abuse (8.6) was higher than that among women with somatic diagnoses with a negative history of abuse (6.2). That this difference did not attain statistical significance may reflect either the small sample size ($n = 13$) in the former or simply selection of a population of women in whom painful somatic pathology is incidentally, rather than causally, associated with a history of sexual abuse.

These findings provide strong presumptive evidence that nonsomatic pelvic pain is one manifestation of somatization associated with sexual trauma. They do not address the more fundamental question of whether sexual abuse causes pelvic pain or is simply part of a larger pattern of childhood and adolescent abuse, neglect, and chaos. One possible explanation for these findings would be that women who somatize are more likely to exaggerate or fabricate histories of sexual trauma. However, Morrison[32] concluded that there was no objective basis for this assertion and that histories were characteristically consistent, detailed, and verifiable. Whether there is any specificity to the association of genital trauma (as opposed to nonsexual physical abuse) and chronic genital (as opposed to nongenital) pain is a logical and attractive hypothesis that remains speculative at this time. For example, Rapkin et al.[33] has recently reported a higher prevalence of childhood physical, but not sexual, abuse among women with chronic pelvic pain as compared with nonpelvic pain and pain-free control subjects. Although the explanation for the low prevalence of sexual abuse in her series is not clear, her results do emphasize that abuse, whether physical or sexual, may predispose to chronic pain.

A second question posed by this study is whether some of the somatic abnormalities observed in group 1 may actually represent symptoms of underlying psychological disorders rather than primary diagnoses. This is a reasonable objection since high rates of hypochondriasis and obsessive neurosis have been reported in women with conditions such as irritable bowel syndrome.[34] These considerations and the psychological impact of chronic pain undoubtedly help to explain the high mean somatization scores (6.8) in the somatic pain group as compared with previously reported pain-free control subjects (2.0).[1] Nevertheless, the fact that women with somatic diagnoses had a distinct psychosocial and sexual profile at least suggests that the cause and psychogenesis of the psychologic abnormality represented in this group may be different from those associated with nonsomatic pain.

A history of sexual trauma and a high somatization score were found to be predictive of increased risk for nonsomatic pelvic pain. The practical significance of this observation is readily appreciated since it should serve to alert the clinician to patients who should be referred for psychologic evaluation and treatment. We are currently in the process of prospectively validating a simple self-reporting questionnaire that may help in assessment of risk for nonsomatic pelvic pain and psychogenic pain disorders (unpublished data). Meanwhile, it seems clear that hysterectomy is not indicated for treatment of chronic pelvic pain before thorough medical and psychologic evaluation and should be performed only when gross anatomic uterine pathology (such as procidentia or large leiomyomas) that is sufficient to explain the degree of disability has been documented.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Cesarean section by local anesthesia in patients with familial dysautonomia

Joseph R. Leiberman, MD,[a] Adolph Cohen, MD,[a] Arnon Wiznitzer, MD,[a]
Channa Maayan, MD,[b] and Lev Greemberg, MD[c]
Beer Sheva, Jerusalem, Israel

We describe a 29-year-old patient with familial dysautonomia who underwent cesarean section because of severe intrauterine fetal growth retardation. The surgery was done after induction of local anesthesia to avoid the critical and sometimes fatal complications of general anesthesia known in patients with familial dysautonomia. Surgery was uneventful and almost painless. The postoperative period was without complications. Induction of local anesthesia for cesarean section may constitute a suitable alternative in patients with familial dysautonomia. (AM J OBSTET GYNECOL 1991;165:110-1.)

Key words: Familial dysautonomia, Riley-Day syndrome, anesthesia

Familial dysautonomia or Riley-Day syndrome is a rare, autosomal recessive genetic disorder found in the Ashkenazi Jewish population that affects the development of the autonomic and sensory nervous systems. Characteristic signs and symptoms include profuse sweating, vomiting, lack of overflow tears, lung infections after frequent episodes of aspirative pneumonia, scoliosis, cardiovascular instability, impaired heat perception and taste, and decreased sensation of pain.[1]

In the past few patients survived long enough to become pregnant; therefore there is little experience with delivery reported in the medical literature.[1, 2] Anesthesia for surgical delivery in these patients presents particular problems. Increased morbidity and mortality were found in subjects with familial dysautonomia who required induction of general anesthesia, and dehydration, dysautonomic crisis, intraoperative severe hypotension, and postoperative atelectasis were frequently described.[2] Extradural anesthesia or spinal block are not adequate for the blood pressure lability. We present a patient with familial dysautonomia who was abdominally delivered of an infant after induction of local anesthesia to avoid the risks of the other anesthetic techniques.

Case report

A 29-year-old Jewish nulliparous patient with familial dysautonomia was first seen at 8 weeks' gestation. She worked as a volunteer in one of the hospital offices. Her previous history and signs revealed convulsive disorders during the school years, growth retardation, vomiting, episodes of lung infection, lack of fungiform papillae on the tongue, and dry eyes, all of which indicated mild familial dysautonomia. Three years before pregnancy a chest roentgenogram was normal. The final diagnosis of familial dysautonomia was made by a pathologic histamine test. The patient was pale; height was 145 cm and weight was 40 kg. She had speech difficulty, infrequent heavy coughing, and postural hypotension. Blood pressure measurements were 150/90 mm Hg while supine and 75/40 mm Hg while standing. Previous gynecologic anamnesis was unremarkable. Menses started at the age of 12 years and were regular (4 to 5 days every 30 days). Vomiting during pregnancy was infrequent. Successive control visits revealed a normally developed pregnancy. Hemoglobin level was 11 gm/dl, and the patient took multivitamin and mineral capsules. Amniocentesis was done at 16 weeks' gestation and revealed normal fetal karyotype and amniotic fluid level of α-fetoprotein.

Several episodes of hypotension occurred at home on hot days and prompted hospitalization. Biochemical tests and arterial blood gas values were in the normal range. Simple hydration was enough to restore blood pressure and a well feeling. At 34 weeks' gestational age, fetal growth retardation was established sonographically. Fetal weight was calculated as 1520 gm (less than the 10th percentile). Nonstress test revealed a normal fetal heart rate. At 36 weeks' gestation severe fetal deterioration was diagnosed and we decided to terminate the pregnancy abdominally. In light of the serious risk of induction of general anesthesia in these patients, cesarean section after induction of local anesthesia was suggested. A team of anesthetists was ready at the surgical theater to induce immediate general anesthesia if required.

Local anesthesia was induced by 1% lidocaine hydrochloride solution. Subcutaneous infiltration was

6/1/28312

made at both sides of a longitudinal infraumbilical incision. Subsequently, every layer was infiltrated. The abdominal wall was opened almost without any complaints by the patient. The approach to the uterus was slightly painful. The anesthetic agent was injected into the myometrium before it was incised transversally in the low segment. At this time the patient's talk showed confusion for a few minutes. A living female infant was delivered through the placenta with Apgar scores of 8 at 5 minutes and 10 at 10 minutes. The infant birth weight was 1630 gm, and results of the physical examination were normal. After extraction of the placenta, suture of the uterine wall required administration of additional local anesthetic agent. Closure of the abdominal wall was performed as usual. For the skin suture lidocaine was added. At the end of the operation the patient was happy and content. The postoperative period was simple and uneventful.

Comment

Familial dysautonomia (Riley-Day syndrome) is a rare disease. The experience with pregnant patients is sparse and only two deliveries by cesarean section were reported in the literature,[2] both of which were performed after induction of general anesthesia. Familial dysautonomia constitutes an anesthetic hazard and increased morbidity and mortality were reported. Cardiovascular lability, respiratory depression, and atelectasis, are grave complications described in surgery with induction of general anesthesia. Adequate hydration and careful titration of anesthetic agents were recently recommended to minimize intraoperative and postoperative complications.[2] Although attractive, neither extradural nor spinal block is the prefered method to induce anesthesia in patients with dysautonomia because of cardiovascular instability.

In our patient the difficulties and risks of induction of general anesthesia were obviated by induction of local anesthesia. Induction of local anesthesia by infiltration is a useful technique that may be indicated in high-risk patients. Cesarean section was performed without trouble with lidocaine 1%, a rather high concentration, as a local anesthetic agent. Although lidocaine by intravenous route is commonly used at the dose of 1 to 5 mg/kg, higher doses may be considered when other means of administration are used. The main adverse effects of lidocaine are on the central nervous system, and it may be that the slight confusion of the patient during surgery was a result of the anesthetic agent. Because a large quantity of anesthetic solution is needed, it may be recommended in future cases to use lidocaine solution 0.5% with epinephrine to slow absorption and reduce untoward effects.

Because of greater understanding of the disease and better treatment today, more patients with familial dysautonomia reach adulthood and can get pregnant. It is our conclusion that when cesarean section is required, induction of local anesthesia may constitute a prefered alternative in these patients.

Tumor necrosis factor-α and interleukin-1β production by human fetal Kupffer cells

William H. Kutteh, MD, PhD,[a] William E. Rainey, PhD,[a] Bruce Beutler, MD,[b] and Bruce R. Carr, MD[a]

Dallas, Texas

This study describes the isolation and characterization of human fetal Kupffer cells. We demonstrated that these cells have the potential to respond to cytokines and lipopolysaccharide with an increased production of tumor necrosis factor-α and interleukin-1β. Kupffer cells were characterized by: (1) morphologic characteristics after adherence to plastic, (2) staining for α-naphthyl acetate esterase, (3) immunofluorescence with monoclonal antibodies, and (4) phagocytosis of latex beads. More than 90% of the adherent cells were identified as macrophages. Kupffer cells cultured with lipopolysaccharide were able to produce interleukin-1β and tumor necrosis factor-α in a time- and dose-dependent fashion and maximal secretion was observed with the use of 10 μg of lipopolysaccharide per milliliter within 8 hours of treatment. We have demonstrated mature functional activity of human fetal Kupffer cells at an early gestational age (13 to 19 weeks) and discussed the roles that these cells may play in development and protection of the fetus. (AM J OBSTET GYNECOL 1991;165:112-20.)

Key words: Kupffer cells, interleukin-1β, tumor necrosis factor-α, human fetus

Kupffer cells, which represent the largest population of resident tissue macrophages in the adult,[1] play major roles in antigen processing and elimination, detoxification of endotoxin, secretion of cytokines, mediation of multiple immune reactions, maintenance of hepatocyte stability and function, and lipid and cholesterol homeostasis.[2, 3] In humans the fetal liver, as a fraction of body mass, is large compared with that of the adult. The liver represents approximately 10% of the total fetal weight at 10 weeks' gestation.[4] The human fetal liver has a diverse cellular composition with about 60% parenchymal cells (hepatocytes), 20% nonparenchymal cells (including Kupffer cells and fat storing cells), and 20% hematopoietic cells.[5]

Although the presence of Kupffer cells at early stages of human development is well documented,[6-10] the functional capabilities of these cells have not been clearly determined. Kupffer cells have been identified in sinusoid-like structures at 5 weeks' gestation and were present in fully developed sinusoids between 6 to 8 weeks.[6, 7] Macrophage precursors, originating from the yolk sac, have been identified in fetal liver at 9 to 10 weeks postconception.[8] It has been suggested that these cells function in removal of debris as one maturing embryonic tissue replaces another.[9] Indeed, yolk sac macrophages from 7-week gestations were noted to contain primitive erythroblasts.[10]

In the adult, Kupffer cell functions are well defined, and they play important roles in the clearance of biologically harmful materials, including bacterial lipopolysaccharide, microorganisms, and clotting factors.[11] Furthermore, endotoxin, derived from enteric bacterial flora, is a normal component of portal venous blood but is efficiently removed during passage through the liver by Kupffer cells.[3, 11] In addition, it is clear that Kupffer cells secrete a wide variety of cytokines that may modify immune functions, including interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), hepatocyte stimulating factor, and interferons.[12-15]

Important roles for fetal Kupffer cells in immune homeostasis have been proposed. Production of the important immunoregulary peptide TNF-α can be induced with endotoxin in fetal and newborn rat hepatic macrophages, demonstrating functional activity of fetal rodent Kupffer cells.[16] TNF-α exhibits diverse activities that can range from local mediation of cellular or tissue homeostasis to systemic events resulting in alterations of physiologic processes. These diverse activities depend on the concentration of TNF-α at the cellular, tissue, or systemic level.[17] Isolated monocytes from cord blood of preterm neonates produced significantly less TNF-α when stimulated with lipopolysaccharide than

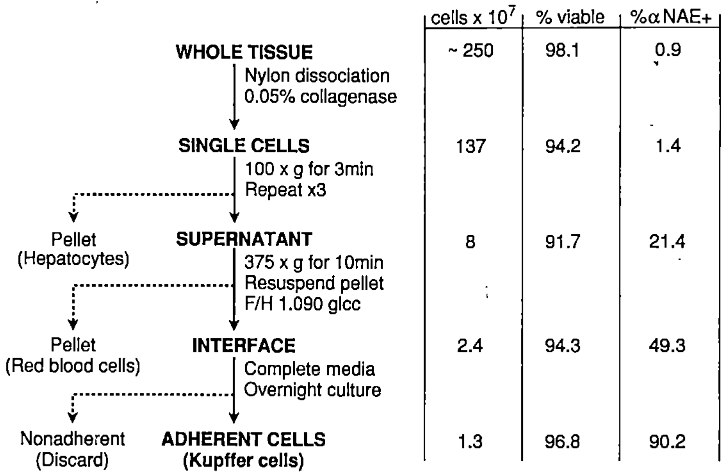

Fig. 1. Kupffer cell isolation procedure. Kupffer cells were purified from specimens of whole human fetal liver as outlined in text. Mechanical and enzymatic dissociation into single cell suspensions, followed by several centrifugation steps, preceded placing cells into overnight culture. Columns refer to total cells in a representative preparation, their viability as determined by trypan blue dye exclusion, and percentage of cells that were positive with α-naphthyl acetate esterase *(NAE)* staining. See Material and methods for details.

monocytes from term neonates, suggesting that this decreased responsiveness may contribute to the increased susceptibility of the preterm neonate to infection.[18] However, in pregnant women with preterm intraamniotic infection, increased levels of TNF-α in amniotic fluids may result in preterm rupture of the membranes.[19, 20]

We hypothesized that Kupffer cells that are obtained from fetuses at 13 to 19 weeks' gestation might possess functional activities that could be important in the development and protection of the fetus. The purposes of this investigation were (1) to develop isolation and purification techniques, (2) to establish short-term culture, (3) to characterize the functional activities, and (4) to investigate potential activators of human fetal Kupffer cells. Purified Kupffer cells could be stimulated to produce IL-1β and TNF-α. We describe a number of activators of fetal Kupffer cells and discuss the potential local (paracrine and autocrine) and systemic (endocrine) effects of these secreted mediators.

Material and methods

Human fetal tissues. Fetal tissues were obtained at the time of therapeutic termination at 13 to 19 weeks' gestation, as determined by fetal foot length. Tissues were obtained in accordance with the Donors Anatomical Gift Act of the state of Texas. A consent form and protocol approved by the Institutional Review Board of the University of Texas Southwestern Medical Center at Dallas were used.

Kupffer cell isolation (Fig. 1). Methods used for the isolation of Kupffer cells from human fetal liver were based on published principles.[21, 22] Fresh tissue was rinsed in calcium-free phosphate-buffered saline solution, pH 7.4, with penicillin (0.1 mg/ml), streptomycin (100 μm/ml), and amphotericin (2.5 μg/ml). The liver was puncture perfused in calcium-free buffer to disrupt the desmosomal attachments of parenchymal cells,[23] then minced into 1 cm^3 pieces in 25 mmol/L HEPES with 5 mmol/L calcium buffer (pH 7.5) containing 0.05% collagenase type IV (Sigma, St. Louis) for 10 minutes at 25° C. The pieces were dissociated between layers of nylon mesh in RPMI 1640 (Gibco, Grand Island, N.Y.) with 2% heat-inactivated calf serum (Gibco), filtered through nylon, and centrifuged at 100 *g* for 3 minutes. (This pellet, depleted of Kupffer cells and cell fragments, was used as the source of hepatocytes, as described below). The supernatant, which was enriched for Kupffer cells, was centrifuged at 375 *g* for 10 minutes; then the pellet was resuspended in media, layered onto Ficoll Hypaque 1.090 gm/ml (Whitaker Bioproducts, Walkersville, Md.), and centrifuged at 350 *g* for 40 minutes at 20° C. The buffy interface was removed, rinsed three times, resuspended in RPMI 1640 with 10% fetal calf serum and antibiotics, and then placed into culture plates as described below. Cytocentrifuge preparations of various cell fractions were stained for α-naphthyl acetate esterase (Sigma), one of the most reliable markers for identification of macrophages.[11]

Hepatocytes. The pellet containing hepatocytes was treated with 0.5 mmol/L ammonium chloride buffer at 0° C for 5 minutes to lyse red blood cells. Hepatocytes were rinsed three times, then resuspended into equal volumes of Dulbecco's modified Eagle medium and Ham's nutrient mixture F-12 with 2 mmol/L L-glutamine (DME/F12, Gibco), 5% calf serum, and antibiotics. An enzyme-linked immunosorbent assay for α-fetoprotein (AFP), a product of fetal hepatocytes, was performed on cell supernatants with commercially obtained assay kits (Pharmacia, Piscataway, N.J.). Interassay coefficient of variation was <2.0%, while interassay variation was <4.8%.

Tissue culture. Kupffer cells were plated at a concentration of 2 × 10^6 cells per well onto 24-well tissue culture plates (Costar, Cambridge, Mass.) and incubated overnight at 37° C in 95% air and 5% carbon dioxide. The following day nonadherent cells were aspirated, wells were rinsed, and then 1.0 ml of complete medium was added to each well. In preliminary experiments the remaining adherent cells were counted after trypsin detachment and numbered as 1 × 10^6 cells. In certain experiments lipopolysaccharide from *Escherichia coli* 026:B6 (Sigma) was added at 0.5 to 10 μg/ml. Each experimental point was performed in triplicate, assayed in duplicate, and repeated at least five times. To determine the phagocytic capacity of the Kupffer cells, latex polystyrene beads, 0.8 μm (Sigma), or Fluorobrite latex beads, 1.75 μm (Polysciences, Warrington, Pa.), were added to adherent cells and incubated for an additional 30 minutes under the conditions described above. Cells were considered positive if ≥10 latex beads were localized intracytoplasmically by direct microscopy. Hepatocytes were plated at a concentration of 4 × 10^6 cells per well onto 24-well tissue-cultured plates (Costar) and incubated overnight at 37° C in 95% air and 5% carbon dioxide in DME/F12 medium with 5% calf serum and antibiotics. Nonadherent cells (approximately 75%) were aspirated, and then adherent cells washed and 1.0 ml of complete DME/F12 medium was added to each well before experiments were initiated. All media, calf sera, and solutions used in these experiments were tested for the presence of bacterial lipopolysaccharide as determined by the *Limulus* amebocyte lysate assay (Sigma) with a modification capable of detecting picograms of endotoxin contamination.[24] We were unable to detect endotoxin with this assay in any of our media, fetal calf sera at 20%, or other solutions used in these studies.

Other materials. Cell viability was determined by the ability to exclude 0.5% trypan blue (Flow Laboratories, McLean, Va.). Recombinant human interferon gamma 2.9 × 10^7 viral inhibition units per milligram, human insulin-like growth factor I, and rat insulin-like growth factor II were obtained from Collaborative Research (Bedford, Mass.). The following human recombinant interleukins and their stated activity were obtained from Research and Diagnostics Systems, Minneapolis: IL-1α (≥5 × 10^8 units/mg in the lymphocyte-activating factor assay); IL-1β (≥5 × 10^8 units/mg in the lymphocyte-activating factor assay); IL-3 (median effective dose of 0.5 to 1.0 ng/ml in the AML-193 incorporation assay); IL-6 (median effective dose of 0.5 to 3.0 ng/ml in the T1165.85.2.1 incorporation assay); TNF-α (≥2 × 10^7 units/mg in the L929 cytotoxicity assay); and TNF-β (>2 × 10^7 units/mg in the L929 cytotoxicity assay). Endotoxin level was determined to be <0.2 ng per 1.0 μg of cytokine by the manufacturer. Recombinant human epidermal growth factor and platelet-derived growth factor were obtained from Imcera Bioproducts, Inc. (Terre Haute).

Immunofluorescence. Monoclonal antibodies against human macrophage or monocyte cells were as follows: EMB-11 (Dakopatts, Glostrup); 3C10 (American Type Culture Collection, Rockville, Md.); anti-Leu-M5 (CD11c) and anti-Leu-M1 (CD15) (Becton-Dickinson, Mountain View, Calif.). Monoclonal antibodies against high-density determinants on human T cells were the following: anti-Leu-2a (CD8), anti-Leu-3a plus anti-Leu-3b (CD4), and anti-Leu-4 (CD3) plus anti-Leu-5b (CD2) (Becton-Dickinson). Cells were incubated with the primary antibody for 30 minutes, washed, and then incubated with fluorescein-labeled F(ab')$_2$ fragment of antimouse IgG (heavy and light chain) adsorbed with human, bovine, and horse immunoglobulin (American Qualex International, La Marata, Calif.). Cells prepared on a Cytotech centrifuge (Miles, Elkhart, Ind.) or cultured on microscope slide chambers (Flaskette, Miles Laboratories, Inc., Naperville, Ill.) were examined with a Leitz-Orthoplane microscope (Rockleigh, N.J.) with a super-high-pressure mercury lamp. Purified mouse immunoglobulin (Becton-Dickinson) was used as a negative control, with indirect immunofluorescence on fetal Kupffer cells and on Ficoll-Paque–purified mononuclear cells from adult peripheral blood. Each monoclonal reagent was tested at various dilutions and then incubated with peripheral blood mononuclear cells, as described, to determine ideal conditions and to serve as a positive control.

Assays for TNF-α and IL-1β. Two well-characterized products of macrophages include TNF-α and IL-1β. Commercially obtained enzyme-linked immunosorbent assay kits for IL-1β and TNF-α (Research and Diagnostic Systems, Minneapolis) with sensitivities of 5 pg/ml were used to assay Kupffer cell supernatants. Intraassay coefficients of variation were TNF-α, <8.0%; IL-1β, <3.0%. Interassay coefficients of variation were: TNF-α, <8.0%; IL-1β, <6.0%. In addition, TNF-α bioactivity was confirmed in certain experiments using an 18-hour cytotoxicity assay on the mouse fibroblast cell line L929 (American Type Culture Collection) as described in detail previously.[19] Recombinant human sequence TNF-α (Research and Diagnostic Systems) was used to standardize measurement of TNF-α activ-

ity. Specific monoclonal antibody to TNF-α (Chiron Corp., Emeryville, Calif.) was able to completely neutralize the cytolytic activity attributed to TNF-α.

Results

Purification of human fetal Kupffer cells. Fig. 1 outlines the purification scheme for human fetal Kupffer cells. The final preparations were >95% viable as assessed by trypan blue exclusion, and >90% were judged to be macrophages on the basis of the ability to ingest 0.8 μm latex beads, α-naphthyl acetate esterase staining, and immunofluorescence with monoclonal antibody 3C10 (Fig. 2, *a, b,* and *c*). Fig. 2, *a,* demonstrates an adherent Kupffer cell after incubation with 0.8 μm latex beads and extensive washing to remove noningested beads. Phagocytosis of multiple beads in the cytoplasm was characteristic of adherent cells. Fig. 2, *b,* is representative of α-naphthyl acetate used as substrate to reveal the dark-stained cytoplasm identifying esterase activity in Kupffer cells. This photomicrograph is from a population of cells just before placement into culture, where typically 50% of the cells were positive. Fig. 2, *c,* is a photomicrograph of adherent Kupffer cells visualized with indirect immunofluorescence staining techniques with mouse monoclonal antibody 3C10. Typically, >90% of adherent cells were positive with this method. Similar immunofluorescence staining patterns were obtained with the use of mouse monoclonal antibodies EMB-11 and anti-Leu-M5. Less than 1% of the adherent cells were positive when stained with monoclonal antibodies anti-Leu-2a, anti-Leu-3a + 3b, or anti-Leu-4 + 5b, indicating that our populations contained very few human T cells (data not shown).

Effect of lipopolysaccharide treatment on TNF-α, IL-1β, and AFP production by human fetal liver cells. TNF-α, IL-1β, and AFP were quantified in the culture media of 1 × 10^6 adherent human fetal Kupffer cells incubated with 10 μg lipopolysaccharide per milliliter of complete culture media for 24 hours. In addition, we assayed the same products in the culture supernatants of purified human fetal hepatocytes. As shown in Fig. 3, IL-1β and TNF-α were produced by human fetal Kupffer cells in significant quantities after stimulation with lipopolysaccharide. Baseline, unstimulated production was 20 pg/ml/10^6 cells for IL-1β and 30 pg/ml/10^6 cells for TNF-α. Hepatocyte culture supernatants contained very low levels of TNF-α or IL-1β with and without lipopolysaccharide stimulation, indicating minimal contamination with Kupffer cells. As shown in Fig. 3, <30 IU AFP per milliliter per 10^6 cells was detected in culture supernatants of Kupffer cells both with and without lipopolysaccharide, indicating minimal contamination with hepatocytes. Conversely, approximately 1400 IU AFP per milliliter per 10^6 cells could be detected in supernatants from fetal hepatocytes. Lipopolysaccharide treatment had no effect on the production of AFP by hepatocytes.

Time course of IL-1β and TNF-α production by lipopolysaccharide-treated Kupffer cells. To determine the kinetics of the response to lipopolysaccharide, Kupffer cells were incubated for 2 to 48 hours with 10 μg/ml of lipopolysaccharide. Quantities of IL-1β and TNF-α released into culture supernatants were measured by enzyme-linked immunosorbent assay (Fig. 4). Increased production of IL-1β and TNF-α were detected as early as 2 hours after stimulation, and maximal production was achieved by 6 to 8 hours. Points represent the accumulation of IL-1β or TNF-α in the culture medium supernatant up to the indicated times. These data indicate that >90% of the equilibrium concentrations of TNF-α and IL-1β produced by Kupffer cells in vitro were reached in the culture supernatants after 8 hours.

Dose response of IL-1β and TNF-α production by lipopolysaccharide-treated Kupffer cells. We then determined the dose of lipopolysaccharide required to ac-

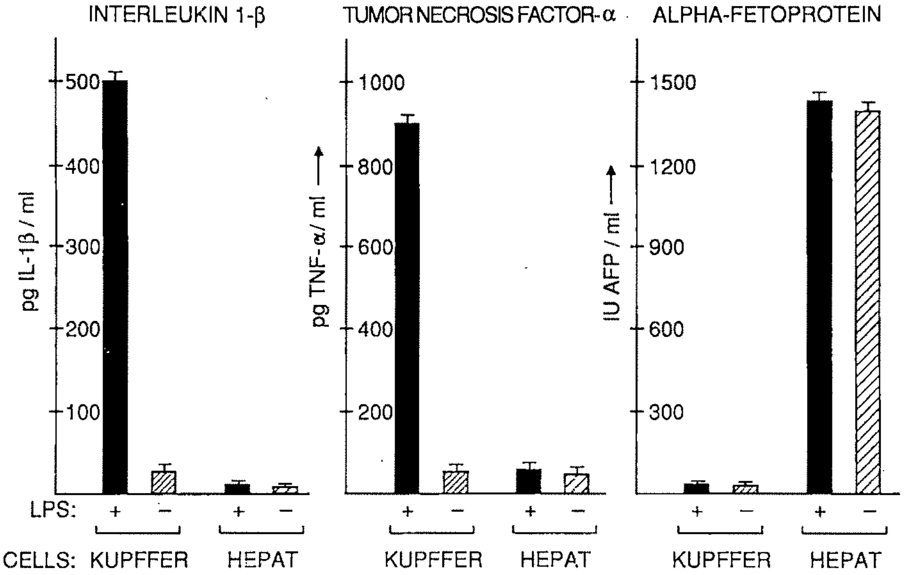

Fig. 3. Production of IL-1β, TNF-α, and AFP by cultured human fetal Kupffer cells and hepatocytes with *(solid bar)* and without *(striped bar)* lipopolysaccharide. Supernatants from overnight cultures of Kupffer cells or hepatocytes (1 × 10^6 cells) were assayed for presence of IL-1β, TNF-α, and AFP. Graph represents one of five similar experiments expressed as mean ± SD.

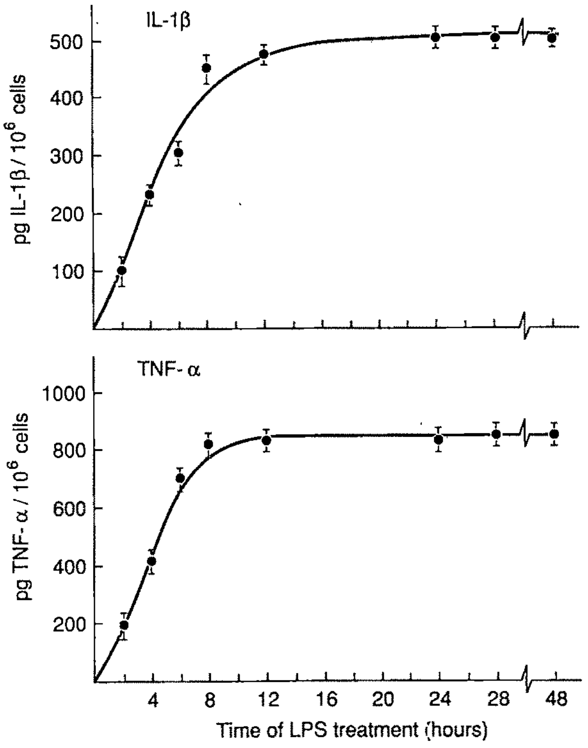

Fig. 4. Time course of IL-1β *(top)* and TNF-α *(bottom)* production by lipopolysaccharide-treated Kupffer cells. After overnight culture, adherent Kupffer cells (1 × 10^6) were washed, then treated with 10 μg/ml of lipopolysaccharide, and quantities of IL-1β and TNF-α were measured by enzyme-linked immunosorbent assay at indicated time points. Figure represents one of five similar experiments expressed as mean ± SD.

tivate Kupffer cells. After incubation for 24 hours with 0.1 to 20 μg of lipopolysaccharide per milliliter, the quantities of TNF-α and IL-1β released into culture supernatants were measured by enzyme-linked immunosorbent assay (Fig. 5). Amounts of TNF-α were noted to increase with as little as 0.1 μg/ml of lipopolysaccharide, with a large increase observed at 0.5 μg/ml of lipopolysaccharide, and a plateau response between 5 and 20 μg of lipopolysaccharide per milliliter (Fig. 5, bottom). Similarly, IL-1β increased in a dose-dependent fashion with a plateau response between 5 and 20 μg of lipopolysaccharide per milliliter (Fig. 5, top).

Effect of growth factors and cytokines in Kupffer cell production of TNF-α (Fig. 6). To determine whether other factors have the potential to activate Kupffer cells, we incubated purified cells with specific growth factors and interleukins for 24 hours and measured the quantities of TNF-α released into culture supernatants. As shown in Fig. 6, IL-1α and IL-1β were able to stimulate Kupffer cells at concentrations of approximately 1.0 ng/ml (10^{-9} to 10^{-10} mol/L). Because several recent reports indicate that IL-6 may serve as an intermediate for IL-1 action in certain cell types,[25] we tested the ability of IL-6 to activate fetal Kupffer cells. The Kupffer cells could also be stimulated to release TNF-α when incubated with recombinant IL-6, TNF-β, and interferon gamma, but these required 20- to 500-fold higher concentrations. The stimulatory effect on the release of TNF-α was demonstrated to occur in a dose-dependent fashion for each interleukin or interferon shown. Endotoxin levels of each recombinant factor were determined to be <0.2 ng/10 μg of cytokine by the manufacturer. Using a modification of the *Limulus* amebocyte lysate assay capable to detecting picogram quantities of endotoxin contamination,[24] we were unable to detect lipopolysaccharide in any of the cytokines tested. We were unable to detect any TNF-α production after incubation with epidermal growth factor (200 ng/ml), platelet derived growth factor (200 ng/ml), insulin-like growth factor I (200 ng/ml), insulin-like growth factor II (200 ng/ml), or IL-3 (200 ng/ml).

Comment

Studies of the functional capacities of human fetal Kupffer cells are limited. Because of our interest in the development of the human fetus and particularly in the function of fetal liver, we felt that it was important to develop isolation techniques for the study and characterization of fetal Kupffer cells. We report here, for the first time, the methods for isolation of human fetal Kupffer cells to >90% purity. We have characterized these cells by morphologic features, by α-naphthyl acetate esterase staining, and by immunofluorescence staining with mouse monoclonal antibodies known to react with human macrophages and monocytes.[26] We do not believe that the preparations were contaminated with peripheral monocytes since <0.5% of the adherent cells were recognized by anti-Leu-M1, a mouse monoclonal antibody characterized to react with 90% of circulating human monocytes but not with tissue macrophages.[27] In addition, <1% of our adherent cells were recognized by three monoclonal antibodies that detect high-density determinants on human T cells.

On the basis of our estimates approximately 1% to 2% of the cells present in human fetal liver at 13 to 19 weeks' gestation are Kupffer cells. Our estimates are based on α-naphthyl acetate esterase staining and immunofluorescence staining with mouse monoclonal antibody 3C10 on frozen sections and touch preparations of intact fetal liver. These estimates agree with results obtained from a morphometric analysis of rat liver sections by electron microscopy, which determined that 2.1% of liver volume was occupied by Kupffer cells.[5] In addition, studies demonstrate that total hematopoietic cells can account for a significant proportion of the fetal liver mass during the tenth to twentieth gestational week; approximately 1% to 2% of the cells evaluated were macrophages.[7] Similarly, when frozen tissue sections from human fetal liver at 10 to 20 weeks were stained with a panel of mouse monoclonal antibodies reactive with class II antigens, (which recognize cells of either macrophage or lymphoid histologic type but not parenchymal cells or red blood cell precursors), estimates of positive cells ranged between 0.3% and 7.7%.[28] Some of the variability in the estimates of Kupffer cell number has been attributed to macrophage heterogeneity in the fetal liver as a function of maturation.[29] These findings indicate an evolving maturational process of Kupffer cells at 10 to 20 weeks' gestation and could explain our observation that 5% of the adherent cells failed to be recognized by any of the monoclonal antibodies against macrophages or monocytes used in this study.

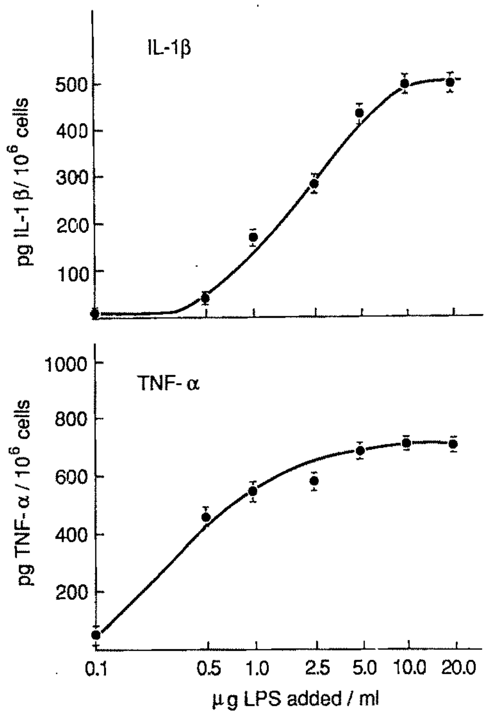

Fig. 5. Dose-response of IL-1β *(top)* and TNF-α *(bottom)* production by lipopolysaccharide-treated Kupffer cells. After overnight culture, adherent Kupffer cells (1 × 10^6) were washed, then treated with indicated amounts of lipopolysaccharide for 24 hours, and quantities of IL-1β and TNF-α released into culture supernatants were measured by enzyme-linked immunosorbent assay. Figure represents one of five similar experiments expressed as mean ± SD.

Functionally, Kupffer cells at 13 to 19 weeks' gestation were able to actively ingest 0.8 μm latex beads in vitro after a 30-minute incubation at 37° C. We have been unable to isolate intact fetal liver from specimens collected before 13 weeks' gestation in quantities sufficient to determine their functional ability. Phagocytosis of particles >0.1 μm has been described as an important criterion to distinguish Kupffer cells from other sinusoidal cells of the liver.[30] In agreement with our findings of active phagocytosis, cells from midgestation human fetal liver that stained positive with OKM-1, a mouse monoclonal antibody to human macrophages, apparently had phagocytosed maternal immunoglobulins or immune complexes, since they contained both immunoglobulin light chain markers, κ

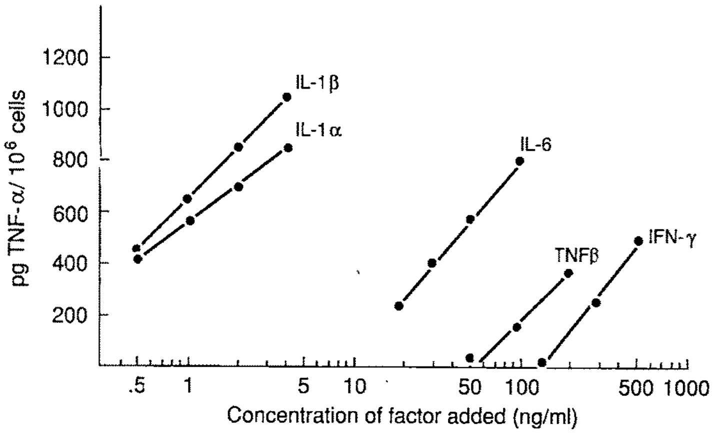

Fig. 6. Effects of several cytokines on Kupffer cell production of TNF-α. Adherent Kupffer cells (1 × 10^6) were incubated for 24 hours with indicated amounts of recombinant IL-1β, IL-1α, IL-6, TNF-β, or IFN-γ, and amounts of TNF-α released into culture supernatants were determined by enzyme-linked immunosorbent assay. Figure represents one of five similar experiments expressed as means. For clarity of publication standard deviations are not shown.

and λ, a situation not described for individual lymphocytes.[31]

Purified fetal Kupffer cells used in this study were stimulated to release both TNF-α and IL-1β with lipopolysaccharide in a dose-dependent fashion (Fig. 5). Similar results were obtained by other investigators when fetal and newborn rat hepatic macrophages were treated with lipopolysaccharide.[16] Similarly, TNF-α and IL-1β were secreted when cord blood monocytes from human preterm and term infants were treated for 24 hours with 10 μg lipopolysaccharide per milliliter.[18] The time course for lipopolysaccharide-stimulated production of TNF-α and IL-1β by human fetal Kupffer cells was similar to those reported by others for adult rat[14, 32] and murine Kupffer cells,[14] human[33] mononuclear phagocytes, and fetal and newborn rat hepatic macrophages.[16] We suggest that the functional activities of human fetal Kupffer cells at 13 to 19 weeks' gestation, including phagocytosis and the production of TNF-α and IL-1β, may be important in the developing fetus. IL-1 has been shown to have direct effects on hepatocytes, endothelial cells, fat-storing (Ito) cells, and Kupffer cells.[34] TNF-α, which has multiple paracrine actions on hepatocytes,[35] may act through specific binding sites that are present on mouse liver membrane preparations.[36]

We sought to identify other factors, in addition to lipopolysaccharide, that might play important roles in vivo by stimulating the production of TNF-α from human fetal Kupffer cells. Both IL-1α and IL-1β were able to stimulate the release of TNF-α when added to fetal Kupffer cells at a concentration of 10^{-9} to 10^{-10} mol/L. IL-1, which mediates the body's response to microbial invasion and inflammation, represents a well-characterized activator of macrophage function.[37] Tamatani et al.[38] have identified IL-1α and IL-1β in normal amniotic fluid of 16- to 18-week pregnancies, indicating the potential of these cytokines to alter fetal Kupffer cell function.[38] The multifunctional cytokines, TNF-α, IL-1α, IL-1β, and IL-6 are produced by macrophages and also have been shown to activate macrophage function.[39] Thus human fetal Kupffer cells would have the potential of being exposed to systemically derived or locally produced cytokines. Although these cells display mature macrophage function in vitro, these data do not provide direct evidence for any in vivo phenomena.

Recent evidence from adult human and animal systems suggests that cytokines may alter hepatocyte function and cholesterol metabolism in vivo by paracrine interactions.[40-42] This is particularly important in the fetus where the liver is the major source of cholesterol in the fetal circulation.[43, 44] Multiple cytokines may alter liver growth and cholesterol metabolism. It has recently been demonstrated that TNF-α, IL-1β and interferon alfa all stimulate hepatic fatty acid synthesis in a rapid fashion, whereas the same cytokines increase hepatic cholesterol synthesis in a delayed fashion.[42] In addition, IL-1β is a potent inhibitor of hepatocyte cell division.[45] These observations, coupled with our findings that TNF-α and IL-1β are produced in human fetal Kupffer cells, suggest a possible role of these factors in human hepatocyte function and cholesterol metabolism by paracrine and autocrine interactions.

In summary, we have purified and cultured human fetal Kupffer cells and demonstrated that these cells possess mature macrophage function. We suggest possible roles of these cells in the clearance of bacterial products, autocrine regulation of immune mechanisms, and paracrine regulation of other immune cells, hepatocytes, and adipocytes. Further work is in progress to determine how these Kupffer cells are activated and how their products might communicate with and regulate cell function in the developing fetus.

We thank Nora V. Cline for technical assistance.

Endothelin production by amnion and its regulation by cytokines

Murray D. Mitchell, DPhil, Sarah Lundin-Schiller, BA, and Samuel S. Edwin, BS
Salt Lake City, Utah

Cells derived from human amnion, an avascular tissue, produced significant amounts of endothelin 1 and 2, although the rate of biosynthesis was approximately one tenth of that of human umbilical vein endothelial cells. Endothelin 1 and 2 was not produced in measurable amounts by cells derived from chorion laeve or decidua. Production of endothelin 1 and 2 by amnion cells was increased by treatment with the cytokines interleukin-1β, tumor necrosis factor, and interleukin-6. The biosynthesis of endothelin 1 and 2 by an avascular tissue is suggestive of a wider role for endothelins than has been recognized. (AM J OBSTET GYNECOL 1991;165:120-4.)

Key words: Endothelin, amnion, cytokine, avascular

Endothelins are a family of small proteins that were originally isolated from the culture supernatants of porcine aortic endothelial cells.[1] Endothelin 1 was originally reported to be a potent vasoconstrictor, and expression of the endothelin 1 gene was found to be regulated by several vasoactive agents. Endothelins 1, 2, and 3 have since been described; endothelin 1 is porcine-human endothelin and endothelin 3 is rat endothelin.[2-4] These 21-residue peptides are formed from a preproendothelin (~200 residues) by way of a 38/39-residue intermediate.[1, 2] It is thought that endothelins act as endogenous agonists of dihydropyridine-sensitive calcium channels.[1] Included among an increasing array of properties of endothelins are the induction of two types of contractions of the rat uterus,[5] activation of phospholipase A,[6] and activation of phospholipase C.[7, 8] Additionally, endothelins recently have been found to be synthesized not only by endothelial cells but also by kidney cells.[9] We have recently found that endothelin 1 is present in amniotic fluid[10] and that its concentration is elevated in amniotic liquor from women with infections of the amniotic fluid who are delivered preterm. This study was undertaken to evaluate potential sources of endothelin 1 within the uterus and to determine whether inflammatory mediators regulate the rate of production of this protein.

Material and methods

Placentas were obtained at cesarean section at term before the onset of labor. Amnion was separated manually and decidua was scraped from the maternal face

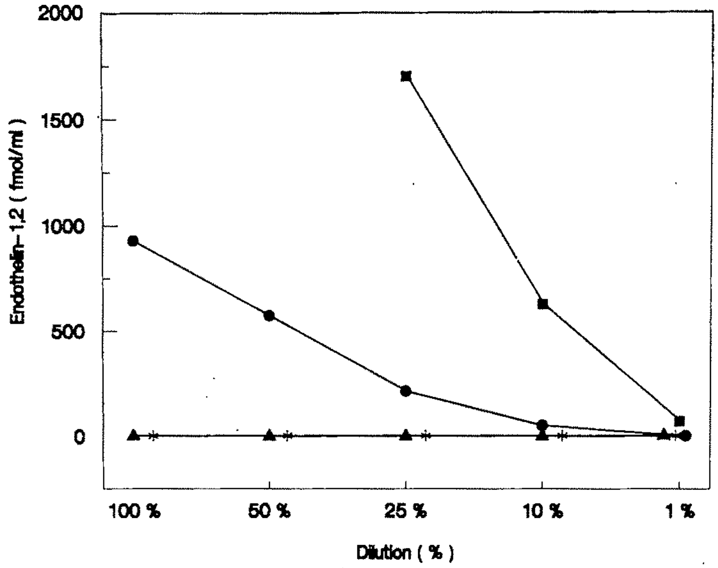

Fig. 1. Endothelin 1 and 2 in dilutions of culture media from amnion, chorion, and decidual cells (initial measurements are concentrates from 50 ml of conditioned media) and umbilical vein endothelial cells (initial measurements are concentrates from 10 ml of conditioned media). *Circles,* Amnion; *triangles,* chorion; *asterisks,* decidual cells; *squares,* umbilical vein endothelial cells.

of the chorion. Cells were prepared from amnion as described previously.[11] Chorion laeve cells were dispersed by treatment with collagenase and isolated by separation of the dispersate on a discontinuous Percoll gradient.[12] Decidual cells also were prepared by collagenase dispersion and isolated on a different discontinuous Percoll gradient.[13] Endothelial cells were prepared from umbilical cords according to the method of Jaffe.[14] Cells were grown to confluence, at which time media for analyses were obtained.

In most experiments culture media were used without manipulation. In one series of experiments culture media were subjected to anisotropic ultrafiltration through a filter with a molecular weight cutoff of 10,000, followed by concentration of the filtrate on a C_{18} Sep Pak (Millipore Corp., Milford, Mass.).[15] Interleukin-1β was purchased from Amgen Biologicals (Thousand Oaks, Calif.); tumor necrosis factor and interleukin-6 were obtained from R & D Systems (Minneapolis).

Endothelin 1 and endothelin 1 and 2 were measured by means of radioimmunoassay kits from Peninsula Laboratories, Inc. (Belmont, Calif.) and Amersham Corporation (Arlington Heights, Ill.), respectively. Cellular protein was determined by the method of Lowry et al.[16] Statistical differences were assessed by Fisher's least significant difference test.

Results

Measurements of endothelin 1 and 2 in serial dilutions of concentrated conditioned media clearly demonstrated secretion of immunoassayable material, not only by endothelial cells (as expected) but also by amnion cells (Fig. 1). Conditioned media from chorion and decidual cells did not contain detectable amounts of endothelin 1 and 2. To establish the relative secretion rates of endothelin 1 and 2 by endothelial and amnion cells, we determined its basal rate of production by confluent monolayers from several individual tissues (Fig. 2). Endothelin 1 and 2 production by endothelial cells was approximately tenfold greater than that of amnion cells.

The antiserum used in the studies at this point, although raised against endothelin 1, cross reacts 200% with endothelin 2 (Amersham Corporation). Hence we could have been measuring either or (more likely) both proteins. We deemed it important to be more specific in our measurements and to evaluate production of endothelin 1 alone. First, we compared measurements of endothelin 1 and endothelin 1 and 2 in conditioned media of amnion cells from several individual tissues under a variety of conditions (Fig. 3). The results indicated a significant correlation between measurements by each method, with endothelin 1 and 2 levels being greater. Although many interpretations of these data are possible, the most obvious is that amnion cells secrete both endothelin 1 and endothelin 2, with endothelin 1 secretion being greatest quantitatively. To evaluate regulation of endothelin 1 production alone, we used the endothelin 1–specific radioimmunoassay (Peninsula Laboratories) in the next series of studies.

Incubation of amnion cells with interleukin-1β and

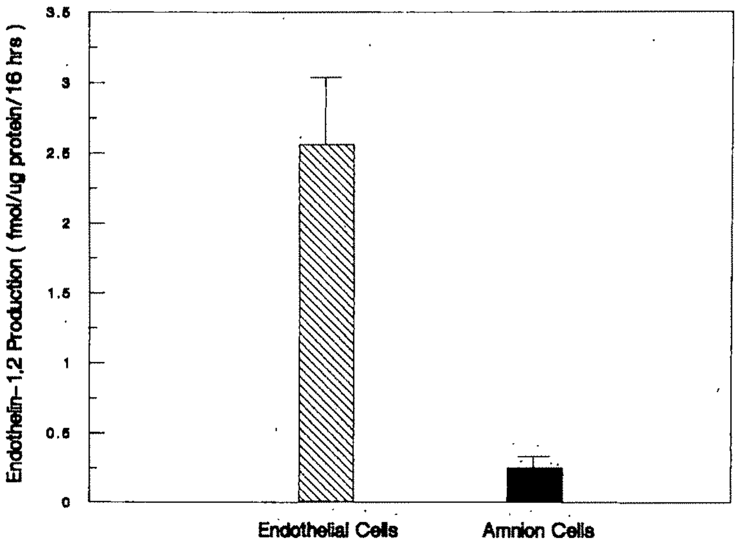

Fig. 2. Endothelin 1 and 2 production (mean ± SEM) by endothelial cells ($n = 6$) and amnion cells ($n = 9$). Difference is statistically significant, $p < 0.005$.

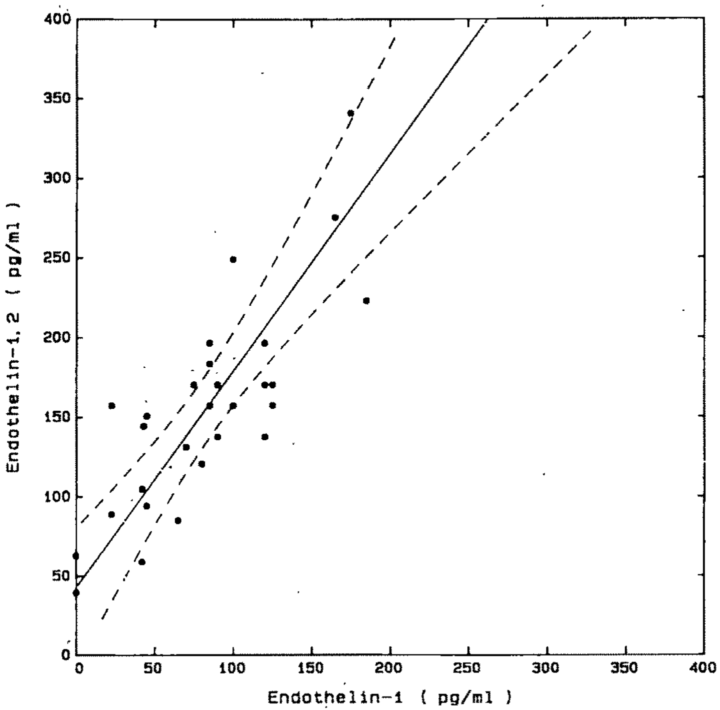

Fig. 3. Comparison of measurements of endothelin 1 and 2 versus endothelin 1 in amnion cell culture media. Linear regression analysis with y = endothelin 1 and 2 and x = endothelin 1 gave $y = 1.69x + 15$; $r = 0.80$.

tumor necrosis factor induced significant increases in the rate of production of endothelin 1 (Fig. 4, *A* and *B*). The results from representative experiments are presented. Similar results have been obtained from experiments with cells from five individual tissues. In contrast, incubation of amnion cells with interleukin-6 resulted in variable effects on endothelin 1 production, although the highest concentration of interleukin-6 used always stimulated endothelin 1 secretion (Fig. 4, *C*). The reasons for this variability are uncertain.

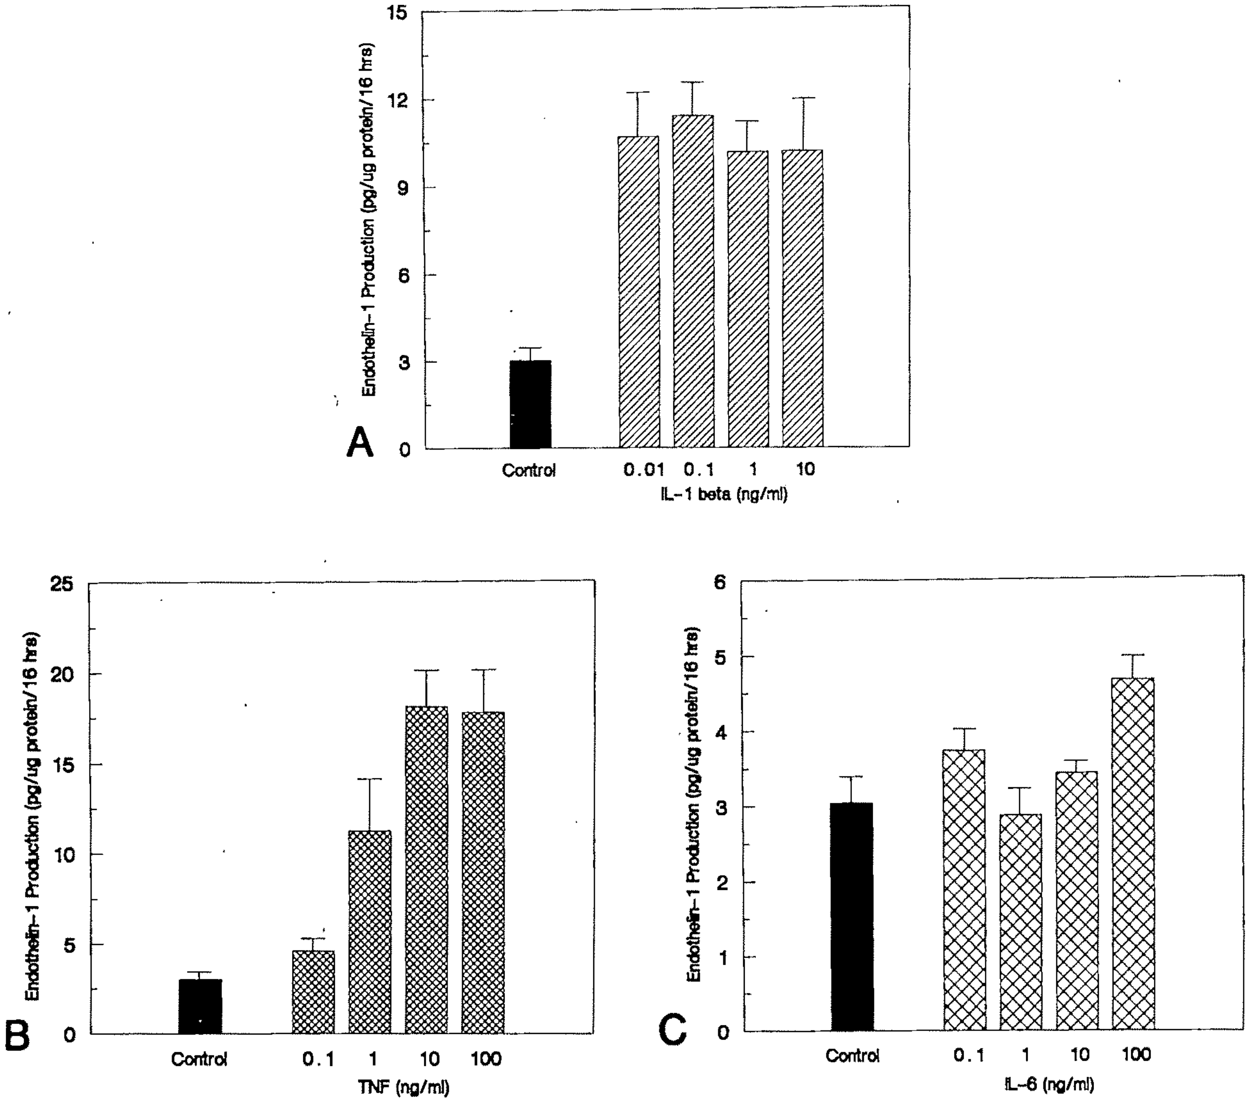

Fig. 4. Effects of cytokines on endothelin 1 production by amnion cells. **A,** Interleukin-1β *(IL-1 beta)*; **B,** Tumor necrosis factor *(TNF)*; **C,** Interleukin-6 *(IL-6)*. Control versus interleukin-1β, $p < 0.005$ (all concentrations). Control versus tumor necrosis factor, $p < 0.005$ (all concentrations). Control versus interleukin-6, $p < 0.002$ at 100 ng/ml.

Similar findings were obtained with endothelin 1 and 2 measurements after cytokine stimulation of amnion cells.

Comment

Our results indicate that endothelin 1 and probably endothelin 2 are synthesized and secreted by avascular amnion. However, it will be important to determine that these proteins have bioactivity, as well as immunoreactivity, and that they are produced by fresh amnion tissue, as well as by cells derived from the tissue. Nevertheless, the data suggest that endothelin production may be more widespread than previously thought. Endothelin production by some cells and tissues may be missed as a result of difficulties in the assay procedure. In our original studies[17] we were often misled by significant matrix effects of different culture media in the assay. Careful attention to the control of these effects was necessary to permit the correct determination of endothelin production by amnion cells.

The increase in amnion endothelin 1 production induced by cytokines is consistent with our finding of raised amniotic fluid levels of endothelin 1 and 2 in pregnancies complicated by intrauterine infections.[10] Moreover, these findings are also consistent with the increase in endothelin messenger ribonucleic acid expression in amnion cells induced by interleukin-1.[18] What role(s) could amnion-derived endothelin 1 serve during pregnancy? Endothelin 1 has been shown to be potent in both elevating cytoplasmic calcium concentrations and increasing myosin phosphorylation in human myometrium.[19] Hence, if endothelin secreted by amnion could reach the myometrium, it could have a significant effect on contractile function. More speculatively, it is possible that endothelin participates in the mechanisms governing amniotic fluid volume. Overall, therefore, our finding of endothelin 1 production by amnion may be of great significance to our future understanding of certain physiologic changes with pregnancy and parturition in women.

Uterine and fetal Doppler flow changes after intravaginal prostaglandin E_2 therapy for cervical ripening

William F. Rayburn, MD,[a] **Joseph C. Anderson, MD,**[b] **Carl V. Smith, MD,**[a] **and**
Lori L. Appel, RDMS[b]
Omaha, Nebraska

Nineteen patients received prostaglandin E_2 as a 2.5 mg gel (seven cases), 3.3 mg chip (five cases), or 10 mg controlled-release pessary (seven cases) for preinduction cervical ripening. Blood flow velocities did not change significantly for the uterine arcuate artery, fetal aorta, and umbilical artery circulations after any of the treatments. In no case did systolic/diastolic ratios consistently elevate above baseline values. (AM J OBSTET GYNECOL 1991;165:125-6.)

Key words: Prostaglandin E_2, Doppler flow, uterine artery, umbilical artery

Low doses of prostaglandin E_2 (PGE_2) instilled intravaginally have become more widely used for preinduction cervical ripening in complicated pregnancies with an unfavorable cervix. Novy et al.[1] reported in the ewe model that PGE_2 exerts a vasoconstrictive effect on the placental bed, decreases umbilical blood flow, and increases fetal arterial pressure. Information is needed in human beings on the effects of PGE_2 on uterine and fetal hemodynamics.

After the study was approved by our Institutional Review Board, gravidas with singleton fetuses at term (37 to 43 weeks' gestation) were enrolled if induction of labor was required and an unfavorable cervix (Bishop score ≤ 4) was present. We have described the measurement of pulsed Doppler flow by the same technician (L.A.) with an aTL Ultramark 4 machine with a mechanical 3.5 mHz transducer.[2] Uterine artery, fetal aortic, and umbilical artery waveforms were sought through use of a combined pulsed real-time B-mode system that allowed precise location for Doppler recording on a real-time image.

After baseline circulatory recordings were obtained, 19 participants were assigned to receive one of three vaginal doses of PGE_2: 2.5 mg in a gel (seven cases), 3.3 mg in a chip (five cases), or 10 mg in a controlled-release pessary (seven cases) as part of a randomized drug trial. Serum concentrations of the principal metabolite of PGE_2 were expected to peak within the first hour, so all measurements were made 15 minutes before dosing, immediately thereafter, and at 15-minute intervals for 2 hours. The flow (velocity-time) waveforms were examined visually and quantitated. A systolic/diastolic (S/D) ratio was then calculated by measuring the ratio of peak systolic Doppler shift to least diastolic Doppler flow. Statistical comparisons were made with an analysis of variance.

Doppler fetal and uterine hemodynamic parameters were not significantly affected by the PGE_2 treatments. The baseline arcuate artery S/D ratio was 1.78 ± 0.28 (mean ± 1 SD), and after PGE_2 instillation the ratio was 1.82 ± 0.34 ($p = 0.45$). The umbilical artery S/D ratio was 2.56 ± 0.60 before PGE_2 administration and 2.46 ± 0.46 after therapy ($p = 0.32$). The fetal aortic velocity was 45.9 ± 14.0 cm/sec and 41.8 ± 11.5 cm/sec before and after PGE_2 treatment, respectively ($p = 0.81$). The power of this study to detect a 25% or greater change in the fetal or uterine Doppler blood flow was 90%. A comparison of PGE_2 chip, pessary, and gel therapies by multiple Student's t tests did not reveal significant differences among any of the modes of drug administration.

In no case was the baseline uterine arcuate artery S/D ratio greater than 2.5. Three fetuses had averaged baseline umbilical artery S/D ratios of 3.0 or greater (3.21, 3.25, 3.81). In no case did absolute values increase or remain elevated on two or more consecutive recordings.

Findings from this investigation revealed no change in the uterine and fetal circulations after short-term exposure to a single intravaginal dose of PGE_2. This observation was true when a presumably rapidly absorbed gel or chip was used. We would assume that the lack of local blood flow change with the controlled-release pessary would continue beyond the first 2 hours after dosing. Results in this study in human beings with the use of a pulsed Doppler system differ from obser-

vations by Novy et al.[1] in the fetal lamb with radiolabeled microspheres. In that study the fetal bradycardia and hypotension found within seconds were followed by hypertension and vasoconstriction of the umbilical circulation shortly thereafter. Furthermore, relatively higher doses of PGE_2 were used, which resulted in higher concentrations than are found in human maternal and fetal plasma at birth.

All 19 of our study cases had pregnancy complications that predisposed the patients to uteroplacental insufficiency. We were reassured to observe no vasopressor effects after PGE_2 dosing, even in the three cases with a previously documented elevated umbilical artery flow resistance. Our observations were limited to term pregnancies, so conclusions cannot be made about the blood flow changes in premature fetuses. This investigation also does not address the safety of sequential doses, but we would assume that this would be safe with adequate time between dosings. As with any drug that may stimulate uterine contractions, close monitoring of uterine activity and the fetal heart rate remain essential.

Does intensive glycemic control in diabetic pregnancies result in normalization of other metabolic fuels?

E. Albert Reece, MD, Donald R. Coustan, MD, Robert S. Sherwin, MD, Susan Tuck, MD, Sue Bates, RN, Theresa O'Connor, MPH, and William V. Tamborlane, MD
New Haven, Connecticut, and Providence, Rhode Island

Intensive treatment of insulin-dependent diabetes mellitus during pregnancy often normalizes plasma glucose levels. However, it is unclear whether this adversely affects other metabolic fuels that are essential to normal fetal growth and development. Metabolic studies were conducted after the subjects ingested a standardized mixed meal during each trimester in 7 normal and 15 insulin-dependent diabetic pregnant women. The latter were treated with continuous subcutaneous insulin infusion or multiple injections, which were adjusted to achieve strict glucose control throughout pregnancy. Insulin, alanine, branched-chain amino acids, triglycerides, free fatty acids, and ketones were measured every 15 to 30 minutes before a standardized breakfast and for 150 minutes after the breakfast. Patients with insulin-dependent diabetes mellitus were studied while they received their usual insulin dosages. Fasting glucose levels (87 ± 7 mg/dl) and glucose levels 150 minutes after the meal (112 ± 11 mg/dl) were near normal. However, normoglycemia was achieved at the expense of increased plasma insulin levels (area under insulin response curves, $p < 0.01$, vs nondiabetic curves). Nevertheless, fasting and post-prandial plasma branched-chain amino acids, alanine, and free fatty acids were similar in both groups. Fasting cholesterol, triglyceride, and ketone levels were also normalized. We conclude that normalization of circulating amino acids and lipids in conjunction with correction of hyperglycemia may contribute to favorable outcomes in infants of intensively treated diabetic mothers. (AM J OBSTET GYNECOL 1991;165:126-30.)

6/1/28313

Marked abnormalities in fuel metabolism are frequently seen in patients with insulin-dependent diabetes who receive conventional insulin therapy. Those abnormalities are probably a result of inadequate insulin replacement. This type of insulin deficiency commonly leads to fasting and postprandial hyperaminoacidemia and hyperlipidemia, as well as hyperglycemia; these effects are compounded in pregnancy by insulin antagonist hormones elaborated by the placenta. Excessive delivery of substrates to the fetus and responsive fetal hyperinsulinemia are generally accepted as important factors that contribute to adverse pregnancy outcomes in poorly controlled diabetic mothers.[1, 2]

Aggressive insulin therapy with either multiple daily injections or continuous subcutaneous insulin infusion is recommended for treating pregnant women with diabetes. Most diabetic women who are strongly motivated to test blood glucose levels frequently (which permits appropriate insulin adjustment) can achieve substantially lower blood glucose values during pregnancy. This treatment prevents or ameliorates some problems faced by the infant of the mother with poorly controlled diabetes. Maintenance of strict treatment goals requires subcutaneous administration of steadily increasing doses of insulin that lead to peripheral hyperinsulinemia and that could, in turn, have adverse metabolic effects. However, relatively little attention has been paid to the effects of intensive insulin treatment during pregnancy on substrates other than glucose. To examine this issue, we measured circulating concentrations of amino acids and lipids both before and after a standardized mixed meal during each trimester of pregnancy in women with and without insulin-dependent diabetes. Our findings suggest that normal concentrations of insulin-sensitive metabolic fuels remain available to the developing fetus of the diabetic mother throughout pregnancy, despite maternal hyperinsulinemia.

Material and methods

Subjects. Fifteen women with C-peptide–negative insulin-dependent diabetes mellitus were studied. These women were recruited from patients referred to the Yale Diabetes-in-Pregnancy Program for intensive insulin treatment. They used either multiple daily injections or continuous subcutaneous insulin infusion. The patients ranged in age from 24 to 32 years (mean ± SD, 28 ± 2 years), in duration of disease from 2 to 21 years (16 ± 4 years), and in White's class from B to FR. They were in good health, were taking no medications besides insulin, vitamins, and iron supplements, and were between 6 and 24 weeks' gestation when they entered the study. Twelve of the 15 patients were studied during each trimester, and the remaining 3 were studied only during the second and third trimesters. Seven patients were treated with multiple daily injections, and eight patients received continuous subcutaneous insulin infusion therapy. Details of outpatient diabetes management and obstetric care have been reported elsewhere.[3] Seven nondiabetic control subjects with an age range similar to that of the pregnant diabetic group were enlisted from a group of healthy pregnant nurses working at the Yale–New Haven Hospital. They were taking no medications other than vitamins and iron, had no family history of insulin-dependent diabetes mellitus or gestational diabetes, and had normal glucose tolerance tests during routine screening at 24 to 28 weeks. Three meal studies (one during each trimester) were performed on each of the control subjects.

Meal study protocol. All meal studies were begun between 7 and 8 AM after an 8- to 10-hour overnight fast. An indwelling catheter was inserted in an antecubital vein, and blood was obtained for measurement of glycosylated hemoglobin, basal substrate, and insulin after a 30-minute rest period. Each subject then ingested a standard mixed breakfast meal prepared by the dietary staff of the Yale General Clinical Research Center. The meal contained 12 kcal/kg of body weight and consisted of 50% carbohydrate, 30% fat, and 20% protein. The meal was designed to approximate what the patients with insulin-dependent diabetes mellitus had been advised to eat at home. Fifteen minutes before they ate, all patients received the same prebreakfast bolus insulin dose that they usually took at home; patients with continuous subcutaneous insulin infusion were maintained on their preprogrammed basal insulin doses. Additional blood samples were obtained for substrate and insulin measurements 30, 90, and 150 minutes after meal ingestion. First-trimester meal studies were performed between 10 and 12 weeks' gestation; second-trimester studies, between 26 and 28 weeks; and third-trimester studies, between 34 and 36 weeks.

Determinations of metabolites. Plasma glucose was measured with a glucose analyzer (Beckman Instruments, Fullerton, Calif.). Standard laboratory techniques were used to determine serum cholesterol and triglycerides, and plasma free fatty acids were assayed by the procedure of Novak.[4] Plasma amino acids were determined by column chromatography,[5] and glycosylated hemoglobin was measured chromatographically with a microcolumn method (Isolab, Akron, Ohio). The reference range in healthy nonpregnant, nondiabetic women for the glycosylated hemoglobin assay was 5% to 8%. Plasma insulin was measured by a double-antibody radioimmunoassay.[6] In the diabetic patients free insulin was measured by precipitating plasma samples at the bedside with polyethylene glycol.[7] Blood ketones were measured by enzymatic assay, and

all measurements were performed within 1 month of study.[8]

Statistical analysis. The data were analyzed to determine the quantitative (area under the curve) and qualitative (shape or pattern of the curve) response of each metabolite to a mixed meal. Repeated-measures analysis of variance was performed; the area under the curve was corrected for baseline differences as the dependent variable. Because the method of insulin replacement (multiple daily injections vs continuous subcutaneous insulin infusion) did not affect the results, data in all subjects with insulin-dependent diabetes mellitus were combined for comparison with data in normal controls. The analysis assessed group differences (subjects with insulin-dependent diabetes mellitus vs controls) and trimester differences. If a significant difference was observed throughout pregnancy by the analysis, the Student t test was used to determine in which trimester (or trimesters) a difference occurred. To examine the pattern of response within each trimester, analysis of variance was also performed; the level of the metabolite at each time period was used as the dependent variable. The analysis was done with the general linear model procedure in the SAS (Statistical Analysis Systems, Cary, N.C.) statistical package. Data are presented as means ± SE.

Results

Mean glycosylated hemoglobin levels were within the range of normal in the patients with insulin-dependent diabetes mellitus during each trimester (Table I) in association with mean fasting and postprandial glucose levels, which also were within our target values (plasma glucose levels, ≤100 mg/dl fasting and ≤120 mg/dl at 2 to 3 hours after a meal) (Fig. 1). Plasma insulin profiles in nondiabetic and diabetic subjects are shown in Fig. 2. In nondiabetic subjects plasma insulin concentrations rose promptly to peak values between 60 and 75 U/ml 30 minutes after the meal and returned to baseline levels by 150 minutes. In contrast, insulin levels rose more gradually in patients with insulin-dependent diabetes mellitus after the premeal insulin bolus (at −15 minutes) and remained above the basal value after 150 minutes. The area under the curve and the pattern of response between patients with insulin-dependent diabetes mellitus and controls were significantly different throughout pregnancy ($p < 0.01$).

Despite differences in plasma insulin, basal and postprandial levels of alanine and branched-chain amino acids (isoleucine, leucine, and valine) were similar in women with insulin-dependent diabetes mellitus and in nondiabetic women during each trimester (Fig. 2). In addition, circulating concentrations of other essential amino acids, including phenylalanine, methionine, and threonine, were not different from normal in the patients with diabetes throughout pregnancy (data not shown). In both diabetic and nondiabetic subjects the area under the curve for alanine increased significantly during pregnancy ($p < 0.01$), and in both groups the integrated area for branched-chain amino acids fell during pregnancy ($p < 0.05$). Basal free fatty acids were slightly (but not significantly) higher in the diabetic pregnant subjects than in the nondiabetic pregnant subjects throughout pregnancy (Fig. 2). Nevertheless, the fall in fatty acids after the meal was similar in both groups. The area under the free fatty acid curve increased significantly in both groups during pregnancy and was greater in the diabetic group than in the control group during the three trimesters ($p < 0.02$).

As summarized in Table I, fasting concentrations of cholesterol and triglycerides increased significantly in both subjects with insulin-dependent diabetes mellitus and in nondiabetic subjects during pregnancy, but there were no significant differences between the groups for either of these lipid fractions. Fasting ketone levels did not differ between the groups or from baseline values within each group during pregnancy (Table I).

Comment

It has become clear in recent years that embryogenesis and fetal development are significantly influenced by the metabolic environment in which the embryo and

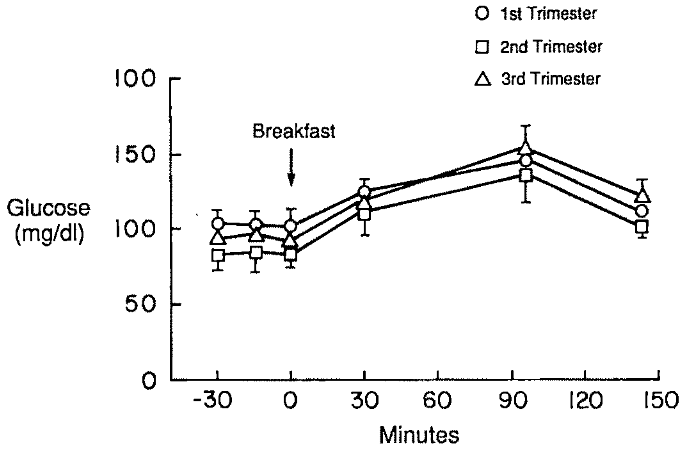

Fig. 1. Glucose profile before and after breakfast in first, second, and third trimesters.

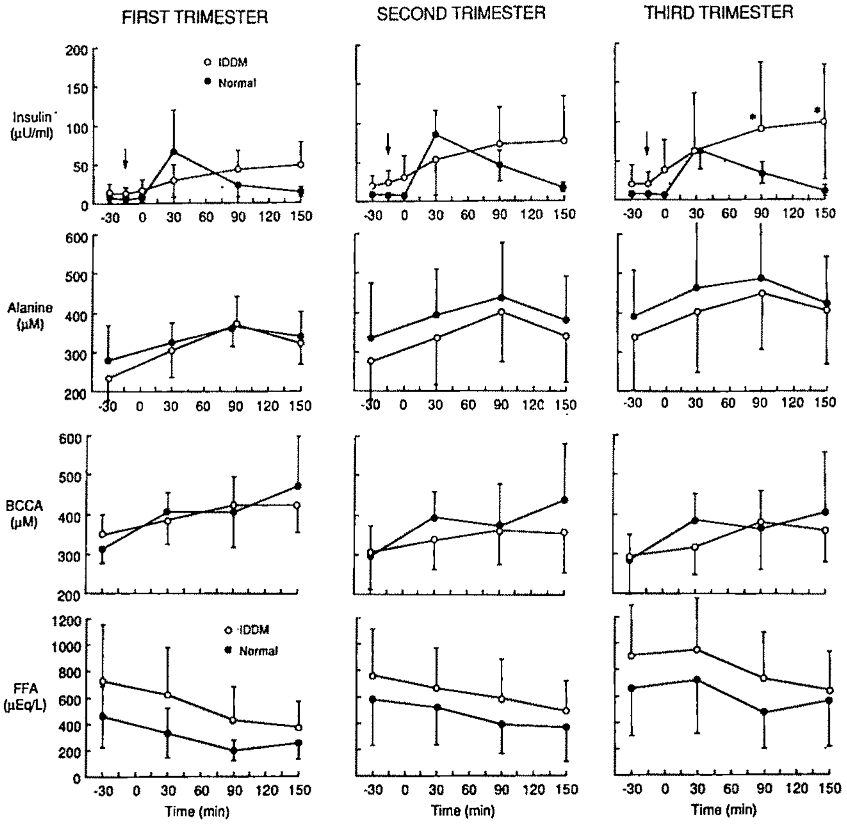

Fig. 2. Metabolic profiles before and after mixed breakfast of insulin, alanine, branched-chain amino acids, and free fatty acids in normal patients and in patients with insulin-dependent diabetes mellitus.

fetus develop. Investigations primarily confined to the effects of hyperglycemia on the developing fetus have shown that adverse outcome results from embryonal or fetal exposure to hyperglycemia. Such exposure during organogenesis leads to malformations[9-11] and is associated with increased perinatal mortality during the third trimester.[12] Experimental studies also have shown that ketone bodies have deleterious effects on the developing embryo.[13] Diabetes mellitus, with derangement of various metabolic fuels (carbohydrates, amino acids, lipids, and ketones), has the potential to adversely affect the developing fetus. Therefore strict glycemic control in pregnancy has become the standard of care in modern obstetrics.

As this study indicates, very strict glycemic control can be achieved in women with insulin-dependent diabetes mellitus during pregnancy via either multiple daily insulin injections or continuous subcutaneous insulin infusion by mechanical pump.[3] Near-normal glycemic control was achieved in our patients, even in the presence of plasma insulin profiles that differed substantially from those observed in nondiabetic pregnant women. Both forms of insulin administration deliver the hormone into the peripheral circulation via the subcutaneous route; therefore it is not surprising that patients with diabetes showed a delayed and markedly prolonged rise in plasma insulin levels when compared with those of nondiabetic subjects. As a result, the integrated insulin area was significantly increased in the diabetic subjects versus the nondiabetic subjects.

A goal of the study was to determine whether failure to precisely simulate plasma insulin profiles in pregnant diabetic women with intensive insulin therapy had adverse consequences for insulin-sensitive metabolic fuels other than glucose. On one hand, peripheral hyperinsulinemia might lead to greater suppression of circulating substrates and might limit their availability to the fetus. Alternatively, the delayed absorption of insulin from the subcutaneous site might fail to correct exaggerated postprandial increments in such substrates, which could contribute to persistent problems, such as macrosomia, in the fetus.[14-16]

It is especially noteworthy that normal basal and postprandial branched-chain amino acid levels were maintained throughout pregnancy in our patients with insulin-dependent diabetes mellitus. Intensive insulin therapy prevented the hyperaminoacidemia (particularly that involving the branched-chain amino acids) that is characteristic of poorly controlled insulin-dependent diabetes mellitus. Furthermore, aggressive insulin therapy in our pregnant patients with insulin-dependent diabetes mellitus was not associated with a fall in plasma branched-chain amino acid levels to subnormal, as was reported in some studies of intensive treatment of nonpregnant patients with insulin-dependent diabetes mellitus.[2, 17] These amino acids are important because they are primarily responsible for muscle nitrogen repletion and are capable of stimulating protein synthesis in vitro. Circulating concentrations of the other essential amino acids, alanine (a key gluconeogenic substrate), and ketones also were maintained within the range seen in pregnant nondiabetic women via intensive insulin therapy during pregnancy. Although free fatty acid levels remained slightly increased in the patients with insulin-dependent diabetes mellitus, these treatments did not significantly alter the changes in fasting cholesterol and triglycerides that were observed in the nondiabetic women during pregnancy.

In conclusion, the use of intensive insulin therapy in pregnant patients with insulin-dependent diabetes mellitus is associated with near normalization (and not suppression) of insulin-sensitive metabolites that are available to the fetus despite the presence of maternal hyperinsulinemia. Infants born to women in this study were free of complications, such as macrosomia, that commonly result from poorly controlled diabetes during pregnancy.[3] It is noteworthy that Kalkhoff et al.[18] have recently shown a direct relationship between maternal plasma amino acid concentrations and birth weight in infants of diabetic and nondiabetic mothers. Thus the influence of intensive insulin therapy on amino acid, lipid, and glucose metabolism may play a role in the generally favorable outcomes of pregnancy that result from these treatments.

The purpose of this study was to determine the effect of labor and chorioamnionitis in interleukin-1 production by human placenta. We studied the activity of the placenta to produce interleukin-1 with an enzyme immunoassay by culturing tissue blocks. The placental tissue obtained after labor produced a larger amount of interleukin-1 than placental tissue obtained before labor. All the placental tissues produced more interleukin-1β than interleukin-1α. The placentas with labor and chorioamnionitis produced about seventeenfold more interleukin-1 than placentas with labor only. We immunohistochemically identified interleukin-1–producing cells in the placenta and found that syncytiotrophoblasts produced both interleukin-1α and interleukin-1β, while Hofbauer cells produced only interleukin-1β. In vitro analysis of the trophoblast activities to produce interleukin-1 revealed that microbial byproducts enhanced interleukin-1 production, possibly inducing accumulation of interleukin-1 receptor–positive cells at the sites of inflammation. In addition to stimulation of prostaglandin biosynthesis and labor, the placental interleukin-1 may act as an inflammatory mediator, leading to systemic and local changes at fetomaternal interface and activating fetomaternal immune systems against intrauterine infection. (AM J OBSTET GYNECOL 1991;165:131-7.)

Key words: Placental interleukin-1, trophoblast, labor, intrauterine infection

A growing body of evidence indicates the contribution of many factors in the onset of human labor.[1-4] Such factors include bacterial endotoxin,[1] bacterial phospholipases,[2] and some cytokines, including interleukin-1[3] (IL-1) and tumor necrosis factor-α,[4] in the case of intrauterine infection. However, our knowledge of the mechanism of the onset of labor in the absence of infection remains incomplete.

IL-1 is a 17 kd glycoprotein that is produced by various kinds of cells, including macrophages.[5] It plays important roles in a number of biologic responses, such as stimulation of the immune response, induction and regulation of inflammatory disease, stabilization of physiologic homeostasis, promotion of cellular proliferation, and differentiation of various cellular systems.[5] Biochemical and molecular analysis of IL-1 has identified two kinds of molecules with similar functions: IL-1α and IL-1β.[6] They perform their unique functions through the same receptors.[7]

IL-1 is one of the most potent regulators of prostaglandin biosynthesis by intrauterine tissue.[3, 4, 8] It also acts as a strong modulator of immune and inflammatory responses.[5] The source of interuterine IL-1 that is responsible for the onset of labor and the mechanisms for and significance of enhanced production of IL-1 in the presence of intrauterine infections are poorly understood. The objectives of the studies described in the present communication therefore were: (1) to measure, by enzyme immunoassay, placenta-derived IL-1α and IL-1β produced by placental explants with or without labor, (2) to examine whether explants with intrauterine infection such as chorioamnionitis show enhanced IL-1 production, (3) to immunohistochemically identify the cells producing placental IL-1, and (4) to analyze the immunoreactivity of trophoblasts in vitro. Our study demonstrates the important significance of placental IL-1 during labor and intrauterine infection in parturition.

Material and methods

Reagents. Human recombinant IL-1α and recombinant IL-β were kind gifts from Dainippon Pharmaceutical Co. (Osaka) and Dr. Y. Hirai of Otsuka Pharmaceutical Co. (Tokushima, Japan). Lipopolysaccharide was purchased from Sigma Chemical Co. (St. Louis). Concanavalin A and *Staphylococcus aureus* Cowan I were purchased from Pharmacia Fine Chemical Co. (Uppsala).

Preparation of tissue explants. For preparation of placental tissue, normal term placentas without medical complications were obtained after vaginal delivery or at elective cesarean section after 38 to 41 weeks' gestation. Immediately after delivery or operation, the decidual tissue was carefully removed and the placenta was minced into 1 mm^3 pieces with sterile forceps. The placentas with chorioamnionitis were prepared similarly. The clinical criteria of chorioamnionitis were as follows: a high fever before delivery with or without other known sites of infection, maternal and fetal tachycardia, uterine tenderness, leukocytosis, and a foul odor of the amniotic fluid.[9] To confirm chorioamnionitis, histopathologic studies of the placentas were performed, as described previously.[9] Histopathologic examination of the placenta and cord demonstrated polymorphonuclear leukocyte or neutrophil infiltration, initially in the extraplacental membranes and later in the chorionic plate and adjacent intervillous space. Control blocks, including ovaries and uteri, were obtained by simple hysterectomy with adenectomy and prepared in a similar way. After thorough washing, the blocks were incubated in a 24-well flat bottom microplate (Corning, Iwaki Glass, Tokyo) at 37° C in a humidified incubator with 5% carbon dioxide in RPMI 1640 medium (Gibco, Grand Island, N.Y.) containing 10% fetal calf serum (Hyclone, Logan, Utah), 100 U/ml penicillin, and 100 μg/ml streptomycin. The culture medium and fetal calf serum were endotoxin-free as determined by the *Limulus* amebocyte lysate test.[3] After incubation the culture was centrifuged at 200 *g* for 10 minutes. The supernatants were removed, filtered through a 0.22 μm Millipore filter (Millipore, Bedford, Mass.), and frozen immediately at −80° C until the time of assay for IL-1. At the end of the incubation period, the tissue was removed and dried completely to determine the dry weight of the tissue. The titers of IL-1 produced by the blocks were expressed as picograms per 1 ml per 1 mg of dry weight of the tissue.

Titration of IL-1 by enzyme immunoassay. The IL-1 titers in the supernatant were determined by enzyme immunoassay kits with monoclonal antibodies that were specific for each of human IL-1α (ANOC 301) and IL-1β (ANOC 205) (Otsuka Assay Research Foundation, Tokushima).[10] The kits are capable of detecting >10 pg/ml of IL-1α and 20 pg/ml of IL-1β, respectively. Interassay and intrassay variabilities of the IL-1α were 4.2% to 6.9% and 6.7% to 7.5%, while those of the IL-1β were 4.2% to 9.5% and 6.7% to 8.9%. Cross-reactivity between IL-1α and IL-1β is not observed. Neither enzyme immunoassay kit is able to detect any of the following cytokines: IL-6, IL-2, tumor necrosis factor-α, granulocyte macrophage colony-stimulating factor, macrophage colony-stimulating factor, interferon beta, or interferon gamma. They are able to detect the exact amount of IL-1 molecules in the presence or absence of fetal calf serum but not in human serum.

Immunohistochemical analysis of IL-1 in the placenta. To determine the localization of IL-1 molecules in the placenta, an immunohistochemical technique was applied, by means of the avidin-biotin-peroxidase complex method (PK-4002, Vectastatin Laboratories, Burlingame, Calif.), as described previously.[11] Briefly, after washing with phosphate-buffered saline solution, either the normal placental block or the block of placenta with chorioamnionitis was quickly frozen in liquid nitrogen. Cryostat sections of the blocks were air-dried, followed by fixation in cold acetone (100%) for 20 minutes and rinsing with phosphate-buffered saline solution. The sections were first bleached in 0.3% hydrogen peroxide to block endogenous peroxidase and then covered with 2% normal horse serum to minimize nonspecific binding. The appropriately diluted monoclonal anti-IL-1α (ANOC 301) and anti-IL-1β antibodies (ANOC 205) were applied at 4° C overnight. After rinsing with phosphate-buffered saline solution, the sections were further incubated for 30 minutes with biotin-labeled horse antimouse immunoglobulin G followed by the addition of avidin-peroxidase complex at 4° C. The sites of peroxidase activity in the sections were visualized with 0.1% 3,3-diaminobenzidine-tetrahydrochloride containing 0.02% hydrogen peroxidase in 0.1 mol/L Tris buffer (pH 7.2). The slides were counterstained lightly with Mayer's hematoxylin.

Preparation of single-cell suspensions of placental cells. To functionally determine the cell suspensions that produce IL-1, single cell suspensions of placental cells were prepared as described previously.[12] Briefly, a placental block was cultured in deoxyribonuclease type I (Sigma) and 0.125% trypsin (Sigma) for 30 minutes at 37° C, followed by application onto a Percoll sedimentation gradient and centrifugation for 15 minutes at 1800 revolutions per minute. Three separate cell populations were obtained. After thorough washing, the middle fraction (5×10^5/ml), which predominantly consisted of trophoblast cells, was resuspended and cultured in 24-well flat-bottom microplates (2 ml per well) (Corning) with fetal calf serum. All the leukocytes and red blood cells in the placenta were collected in the bottom fraction. To further reduce the number of contaminating macrophages, the cells in the middle fraction were cultured at 37° C for 1 hour to let macrophages adhere the plastic dishes.[13] The middle fraction was tested for contamination by macrophages,

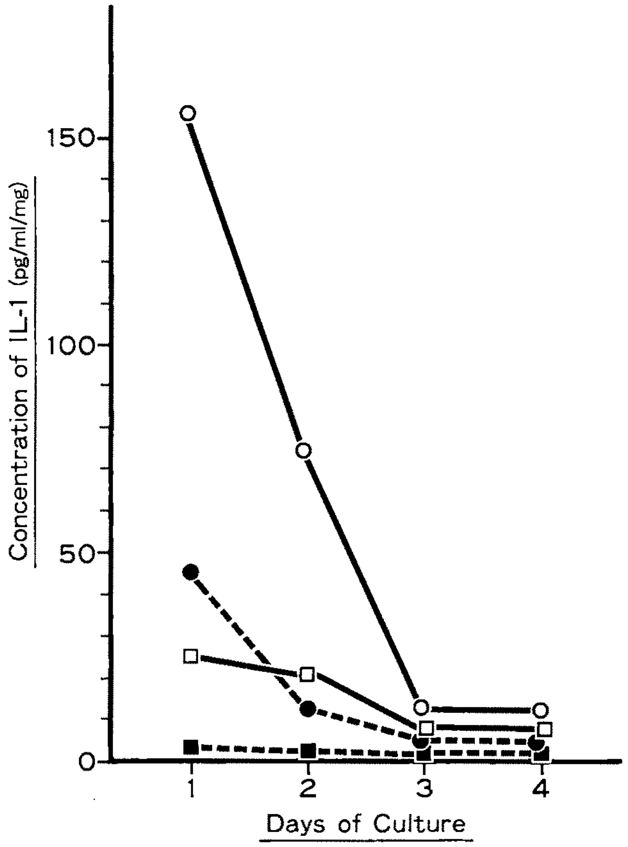

Fig. 1. Time course of IL-1α and IL-1β production by placental blocks with labor ($n = 3$) or without labor ($n = 3$). Blocks were prepared from placental tissues obtained before or after labor. Media were changed every 24 hours and cell-free culture supernatants of the blocks were collected each day. Titers of IL-1α and IL-1β in supernatants were determined by enzyme immunoassay as described in Material and methods. *Open symbols* indicate IL-1α (□——□) and IL-1β (○——○) from placentas with labor, and *solid symbols* represent IL-1α (■——■) and IL-1β (●——●) from placentas without labor. Each titer represents mean; SE was within 15%.

T cells, and B cells by immunofluorescence analysis with KP-1 anti-CD 68 (Dakopatts, Glostrup), Leu 4 anti-CD 3 (Becton-Dickinson, Mountain View, Calif.), and B1 anti-CD 20 monoclonal antibodies (Coulter Clone, Hialeah, Calif.), respectively.

Stimulation of trophoblasts with mitogens. The cells in the trophoblast-enriched fraction were adjusted to 5×10^5/ml and stimulated with the various concentrations of mitogens originally used for the activation of macrophages (lipopolysaccharide), T cells (concanavalin A), and B cells (*S. aureus* Cowan I).[13] Cell-free culture supernatants were collected and filtered at 24, 48, and 72 hours after the stimulation. The culture supernatants were then frozen at −80° C until used for titration of IL-1.

Statistical analysis. The statistical significance of experimental differences was assessed with Student's *t* test for paired data.

Results

Fig. 1 shows the time course of titers of IL-1α and IL-1β produced by the placental blocks obtained before and after labor (each group, $n = 3$). Further culture of either blocks resulted in a decline in both IL-1 titers, showing the highest activity of placentas to produce IL-1 at 24 hours.

Fig. 2 shows that the placental blocks with labor ($n = 15$) produced a statistically larger amount of IL-1α ($p < 0.05$) and IL-1β ($p < 0.05$) than those without labor ($n = 16$) for 24-hour culture. Either block produced predominantly IL-1β rather than IL-1α.

The explants with labor and chorioamnionitis ($n = 3$) produced 328.7 ± 85.3 pg/ml/mg of IL-1α and 1489.0 ± 831.0 pg/ml/mg of IL-1β, titers, which were about seventeenfold higher than those of the blocks with labor only.

Fig. 3 shows the immunohistochemical profile of cell

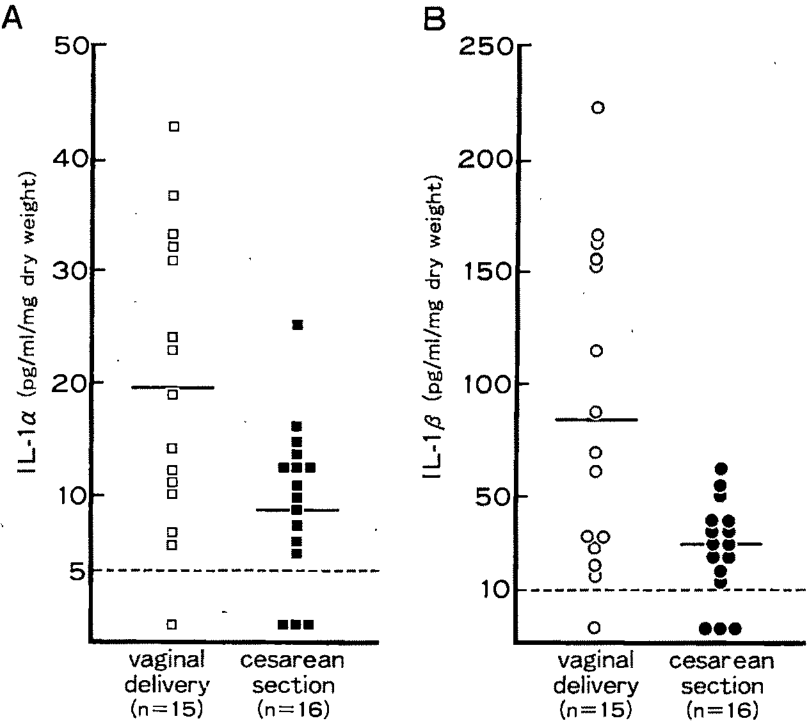

Fig. 2. Production of IL-1α (**A**) and IL-1β (**B**) by placental blocks with or without labor. Supernatants, cultured for 24 hours, were assayed for IL-1α and IL-1β by enzyme immunoassay. *Open symbols* indicate IL-1α (□) and IL-1β (○) from placental blocks with labor. *Solid symbols* represent IL-1α (■) and IL-1β (●) from blocks without labor. *Horizontal dashed bar* represents mean of each experimental group. *Horizontal dotted bar* indicates threshold (5 pg/ml/mg for IL-1α and 10 pg/ml/mg for IL-1β) of assay.

populations in the placenta with labor that produced IL-1α and IL-1β. The outer trophoblast layer, i.e., the syncytiotrophoblast, was positively stained with a monoclonal anti-IL-1α antibody (Fig. 3, *A*). Other cell populations, such as mesenchymal cells and endothelial cells in the placenta, were negative for staining. In contrast, an anti-IL-1β antibody showed that syncytiotrophoblasts and some Hofbauer cells prodcued IL-1β (Fig. 3, *B*). The similar findings were obtained with the explants without labor or with chorioamnionitis (data not shown).

Enhanced production of IL-1 in chorioamnionitis led us to investigate the activity of trophoblasts to produce IL-1 in vitro. Purified normal trophoblasts spontaneously produced a small amount of IL-1 in unstimulated conditions. The trophoblasts showed maximal production of IL-1 for 2 days of culture in response to lipopolysaccharide at doses from 10^{-2} to 10 μg/ml (Fig. 4, *A*) and to *S. aureus* Cowan I at doses from 10^{-4} to 10^{-1} (vol/vol) (Fig. 4, *B*). In contrast, the trophoblasts failed to produce any increased amount of IL-1 by the stimulation with concanavalin A (Fig. 4, *C*). The titer of IL-1α produced by trophoblasts was generally higher than that of IL-1β under these conditions. Purified trophoblasts contained <3% contamination by $CD68^+$ macrophages, $CD3^+$ T cells, and $CD20^+$ B cells, as determined by immunofluorescence analysis. Preterm trophoblasts showed similar immunocompetent activity to produce IL-1 by mitogenic stimulation (data not shown).

Comment

Decidual IL-1 is one source of intrauterine IL-1 and is produced by endotoxin-activated macrophage-like cells.[14] We demonstrated that the placental IL-1 is another source of the intrauterine IL-1. Indeed, there have been some reports demonstrating the presence of placental IL-1 detected by a bioassay for IL-1.[15,16] However, no reports have examined the cause-effect relationship between placental IL-1 and the presence of labor with or without intrauterine infection. We demonstrated the relationship by titration of placental IL-1 with enzyme immunoassay, because IL-1 is composed of two distinct species and the bioassay for IL-1 is easily interfered with by an IL-1 inhibitor that is often present in samples.[17] Furthermore, we immunohistochemically determined the source of IL-1α from syncytiotrophoblasts and IL-1β from syncytiotrophoblasts and Hofbauer cells.

Placentas with labor produced a larger amount of

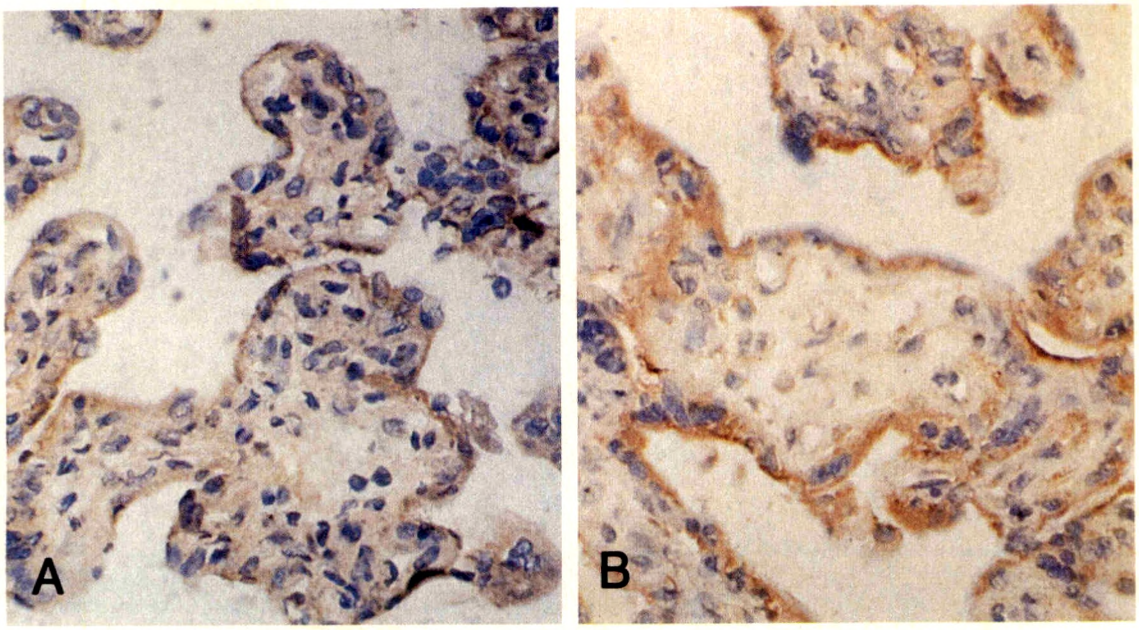

Fig. 3. Immunohistochemical demonstration of IL-1–producing cells in placenta. Freshly frozen placental explants with labor were prepared and stained with mouse monoclonal antibodies against **(A)** human IL-1α (ANOC 301) and **(B)** human IL-1β (ANOC 205) by the avidin-biotin method; they were subsequently counterstained with Meyer's hematoxylin. (Original magnification, ×400.)

IL-1 than the placentas without labor, showing maximal IL-1 production at 24 hours. It is less likely that the placentas with labor produced a higher amount of IL-1, because of the stimulation by bacteria in the vagina and the fact that the placentas were cultured in an endotoxin-free condition. The result was also not due to cell death since there was no significant difference of cell viability between the groups, as determined by the trypan blue dye exclusion test of single cell suspensions from each group. Rather, it is more likely to suppose that the placenta actively produces a baseline level of IL-1 in vivo and that the elevated placental IL-1 directly stimulates the biosynthesis of prostaglandins in the decidua, leading to the onset of spontaneous term labor and delivery. It is unclear, however, what signals regulate placental IL-1 production in an infection-free condition.

The role of IL-1 in amniotic fluid has been suggested to be the signal for the onset of parturition.[3] The intraamniotic IL-1 might be derived from desquamated fetal keratinocytes or decidual cells in infection.[3] However, we showed another possibility that intraamniotic IL-1 is also derived by syncytiotrophoblasts and Hofbauer cells because of transmembrane passage of IL-1[3] from the placenta into the amniotic fluid. Therefore our data support the hypothesis that the placental IL-1 might contribute to the enhanced concentration of intraamniotic IL-1 during labor or intrauterine infection, because the placenta showed increased production of IL-1 in that condition. Thus placental IL-1 might be also involved in stimulation of prostaglandin biosynthesis by amniotic cells, leading to the onset of labor and delivery in another way.

The regulation of IL-1α and IL-1β production has been shown to be controlled by distinct molecular mechanism in IL-1–producing cells.[18] Placental blocks, with or without labor or intrauterine infection, produced a larger amount of IL-1β than IL-1α. However, purified trophoblasts secreted more IL-1α than IL-1β under mitogen-free and mitogen-stimulated conditions. The different pattern with placental blocks might be due to deletion of Hofbauer cells during the in vitro procedure for purification of the trophoblasts. There are also some discrepancies between placental IL-1 level and that of IL-1 in amniotic fluid. IL-1α is higher than IL-1β in amniotic fluid of women with labor, whereas IL-1β is dominant in that of women with preterm labor in intrauterine infection.[3] Complex mechanisms might operate to regulate the fluctuation of IL-1 levels in amniotic fluid.

The systemic and local inflammatory changes in chorioamnionitis might be induced by the actively secreted placental and decidual IL-1[14] with synergistic action of a number of other chemotactic factors.[19] IL-1 acts as a chemotactic agent to induce the accumulation of IL-1 receptor–positive neutrophils at the site of inflammation.[20] The activated neutrophils secrete proteases such as elastase, collagenase, phospholipid A_2, and oxygen radicals, which act as cytocidal agents against invading bacteria.[19] The enhanced production of intrauterine

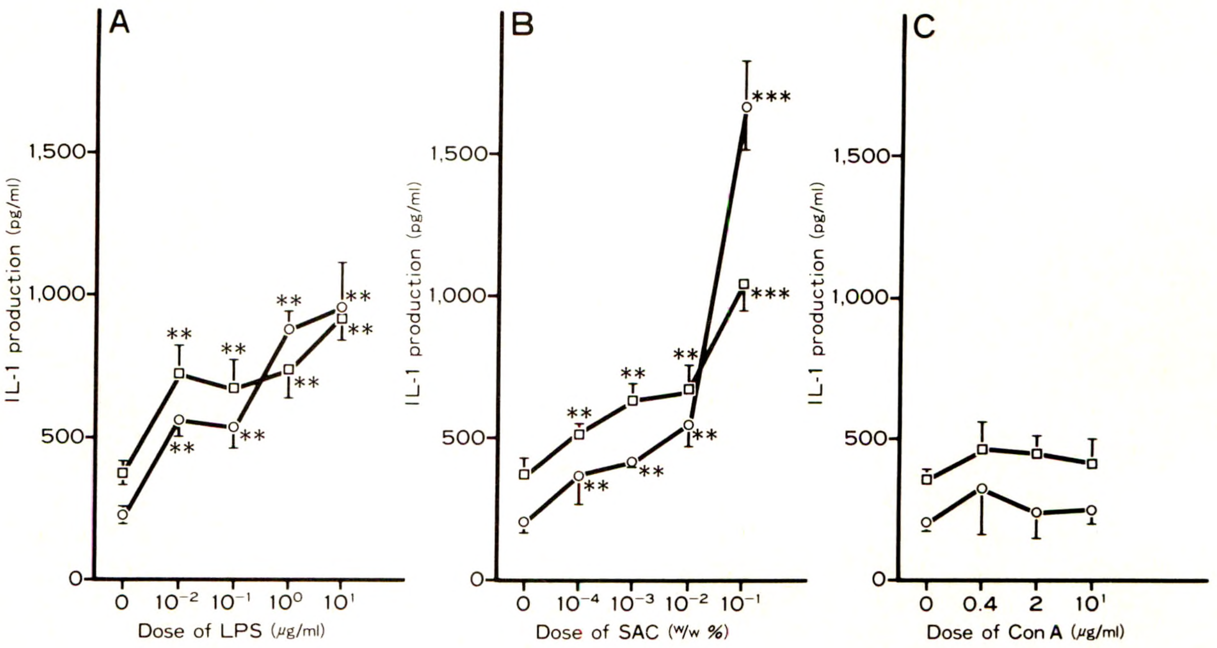

Fig. 4. Production of IL-1α and IL-1β by purified trophoblasts stimulated with mitogens. Trophoblasts were enriched by Percoll density gradient after enzyme (deoxyribonuclease type I and trypsin) treatment of placental blocks without labor. Purified trophoblasts (5×10^5/ml) were stimulated with various concentrations of lipopolysaccharide **(A)**, *S. aureus* Cowan I **(B)**, and concanavalin A **(C)**. After 48-hour culture, cell-free culture supernatants were collected and assayed for IL-1α (□) and IL-1β (○) by enzyme immunoassay. Data represent mean ± SE of triplicate cultures. Three different experiments showed identical results. *Double asterisk*, $p < 0.01$ versus control; *triple asterisk*, $p < 0.001$ versus control.

IL-1 in chorioamnionitis also may activate the fetomaternal immune systems, because T cells and B cells that also express IL-1 receptor are activated, proliferated, and differentiate under such conditions,[21] thus potentiating host (fetal and maternal) immune responses against infections and reducing fetal morbidity and mortality.

By stimulation of purified trophoblasts with mitogens, we developed an in vitro model to investigate the immunologic activities of trophoblasts in the setting of intrauterine infection. Trophoblasts augmented their IL-1 production in response to microbial byproducts including lipopolysaccharide and *S. aureus* Cowan I, both of which would be released by gram-negative[19] and gram-positive microorganisms in intrauterine infection, respectively. Although preparation of purified trophoblasts resulted in contamination by macrophages, T cells, and B cells, the amount of IL-1 potentially produced by these contaminating monocytes, rather than by trophoblasts, was negligible. Trophoblasts showed high responsiveness to both mitogens, whereas human macrophage responds only to lipopolysaccharide and B cells only to *S. aureus* Cowan I.[13] Since trophoblasts can be activated by bacterial endotoxin (lipopolysaccharide) to produce IL-1 in a similar way to the decidual cells,[11] our in vitro experiments with trophoblasts might explain, at least in part, the mechanism responsible for the increased IL-1 production by placentas with chorioamnionitis. Thus the experimental system would be useful for the biochemical and molecular analysis of trophoblast-mediated immunologic functions in intrauterine infection.

IL-1 plays a critical role in initiation and augmentation of host immune systems[5, 22] and possesses the unique activities to stimulate biosynthesis of prostaglandins[3, 4, 8]; therefore we propose that placental IL-1 contributes to potentiation of fetomaternal immune responses against intrauterine infection and promotion of labor not only in term but also in preterm parturition.

We thank Drs. Masahiro Nakayama and Noriyuki Suehara in Osaka Medical Center and Research Institute for Maternal and Child Health for providing us the placentas.

Fibrinolytic parameters in normotensive pregnancy with intrauterine fetal growth retardation and in severe preeclampsia

**Amparo Estellés, MD, PhD,[a] Juan Gilabert, MD, PhD,[b, d] Francisco España, PhD,[a]
Justo Aznar, MD, PhD,[c] and Manuel Galbis, MD, PhD[b]**
Valencia, Spain

In pregnancy a decrease in fibrinolytic activity, which is due to an increase in plasminogen activator inhibitor activity and plasminogen activator inhibitor type 1 and type 2, has been described. Because the placenta is a source of both type 1 and type 2 plasminogen activator inhibitor, we have studied them and other fibrinolytic parameters in a group of normotensive pregnant women with intrauterine fetal growth retardation and in two groups of women with preeclampsia, with or without intrauterine growth retardation. A significant increase in plasminogen activator inhibitor type 1 antigen and plasminogen activator inhibitor activity was observed in preeclampsia, with or without intrauterine growth retardation, but not in normotensive pregnancy with intrauterine growth retardation, when compared with normal pregnancy. Plasminogen activator inhibitor type 2 antigen levels showed a significant decrease in both groups of pregnant women (normotensive or preeclamptic) with intrauterine growth retardation when compared with pregnancies without intrauterine growth retardation. A significant correlation between plasminogen activator inhibitor type 2 levels and fetal weight has been observed in the clinical groups. (AM J OBSTET GYNECOL 1991;165:138-42.)

Key words: Intrauterine growth retardation, preeclampsia, fibrinolysis, plasminogen activator inhibitor

It is generally accepted that perinatal mortality is increased in pregnancies with intrauterine fetal growth retardation (IUGR).[1]

Occlusive lesions in placental vasculature and decidual spiral arteries, named *acute atherosis* or *atheromatous-like lesions*, can be found in normotensive pregnancies complicated by IUGR and pregnancy-induced hypertension (preeclampsia).[2, 3]

A decrease in fibrinolytic activity that is due to an increase in plasminogen activator inhibitor activity, plasminogen activator inhibitor type 1 and type 2, has been described in normal pregnancy.[4-10] Moreover, a depressed fibrinolytic status caused by high levels of plasminogen activator inhibitor type 1 has been described in patients with preeclampsia,[9, 10] and in a previous report[9] we described elevated levels of type 1 in plasma that are positively correlated with the severity of placental damage. On the other hand, reduced levels of plasminogen activator inhibitor type 2 in plasma in patients with preeclampsia have been reported.[9, 11]

Although preeclampsia is commonly associated with small-for-gestational-age infants, IUGR may occur without hypertensive disease, and the severity of fetal growth retardation is correlated with the degree of placental infarction.[3]

Because the placenta is a key source of type 1 and type 2 plasminogen activator inhibitor, we have studied them and other fibrinolytic parameters in normal pregnancy, in normotensive pregnancy with IUGR, and in patients with preeclampsia with and without IUGR.

Material and methods

Clinical groups. The normotensive pregnancy with IUGR group comprised 11 normotensive pregnant women who were diagnosed as having suspected IUGR when serial ultrasonographic measurements of biparietal diameter and femur length were >2 SD below the mean for gestational age two consecutive times in a month.[12] After delivery, diagnosis of IUGR was confirmed when newborn weight was below the 10th percentile of appropriate birth weight for gestational age and neonatal ponderal index was <2.20 (2.01 ± 0.10; range, 1.90 to 2.19).

Sixteen primigravid patients with no previous history of hypertension in whom severe preeclampsia developed during the third trimester comprised the two preeclamptic pregnancy groups. Severe preeclampsia was

*Gestational age–matched controls.

diagnosed in these women when blood pressure was >160/110 mm Hg at bed rest on at least two occasions 6 hours apart.[13, 14] In these patients proteinuria was >1 gm/L in at least two random specimens collected 6 hours apart.[15] Blood samples were taken before treatment. In 10 of the 16 cases a diagnosis of suspected IUGR was made during the third trimester and confirmed after delivery. In all 10 cases the neonatal ponderal index was <2.20 (1.84 ± 0.25; range, 1.35 to 2.18). In the other six cases birth weight was found to be in the normal range for gestational age, and the ponderal index was >2.20 (2.70 ± 0.32, range, 2.40 to 3.20).

The women with preeclampsia with IUGR differed from the other two groups with respect to gestational age at blood sampling. Therefore this group was compared with a gestational age–matched control group (n = 17). The normotensive pregnancy with IUGR group and the preeclamptic group without IUGR were compared with another gestional age–matched control group (n = 26) (Table I). These two control groups included 43 healthy normotensive women in the third trimester of pregnancy. No complications were observed during pregnancy, and the fetal growth was normal. The women did not receive any type of medication except for a vitamin complex.

The normal nonpregnant control group included 18 healthy nonpregnant women (age, 29.5 ± 6.3 years; range, 20 to 40 years) who did not use oral contraceptives and who were nonsmokers.

Blood samples. Blood samples were obtained by venipuncture in the cubital vein and anticoagulated with 3.8% sodium citrate (9:1, vol/vol, blood/anticoagulant). Citrated blood was centrifuged at 1500 g for 15 minutes at 4° C. Samples were collected and stored at −40° C for ≤3 months before assay.

Informed consent was obtained from all women before the blood sample extraction.

Plasminogen activator inhibitor activity assay. The assay for plasminogen activator inhibitor activity was performed as previously described.[4, 9] Briefly, one volume of sample containing plasminogen activator inhibitor was incubated with single-chain tissue-type plasminogen activator (Biopool, Umea) at a concentration of 40 IU/ml for 15 minutes at room temperature. The reaction was stopped by the addition of an equal volume of 1 mol/L sodium acetate buffer, pH 3.9, and the mixture was incubated at 37° C for 20 minutes to inactivate plasma protease inhibitors. The residual tissue-type plasminogen activator activity was then determined by measuring the plasmin activity generated after addition of plasminogen and soluble fibrin, with the chromogenic substrate S-2251 (Kabi Diagnostica, Stockholm). To obtain optimal assay precision, samples were conveniently diluted so that they inhibited 25% to 75% of the activity of the tissue-type plasminogen activator added. Plasma dilutions were performed with tissue-type plasminogen activator/plasminogen activator inhibitor free plasma obtained by immunoaffinity (Biopool).

One unit of plasminogen activator inhibitor activity is defined as the amount that inhibits 1 IU of single-chain tissue-type plasminogen activator in 15 minutes at room temperature under the conditions used. The intraassay and interassay variability was 6% and 9%, respectively.

Plasminogen activator inhibitor type 1 antigen. Plasminogen activator inhibitor type 1 antigen was

t-PA, Tissue-type plasminogen activator; *scu-PA,* single-chain urokinase-type plasminogen activator; *uPA,* urokinase-type plasminogen activator; *PAI,* plasminogen activator inhibitor; *IUGR,* intrauterine growth retardation; *PE,* preeclampsia.

*Results are given as mean ± SD. Range is shown in parentheses.

quantified with a commercially available, enzyme-linked immunosorbent assay (Tint Elize PAI-1, Biopool). This method detects active and latent (inactive) forms of plasminogen activator inhibitor type 1, tissue-type plasminogen activator/plasminogen activator inhibitor type 1 complexes, and urokinase-type plasminogen activator/plasminogen activator inhibitor type 1 complexes with the same efficiency. The intraassay and interassay variability was 4% and 9%, respectively.

Plasminogen activator inhibitor type 2 antigen. Plasminogen activator inhibitor type 2 antigen was quantified by an enzyme-linked immunosorbent assay (Tint Elize PAI-2, Biopool). The assay detects both the low-molecular-weight (48 kd) form and the high-molecular-weight (60 kd) form of plasminogen activator inhibitor type 2. The intraassay and interassay variability was 3.5% and 6%, respectively.

Tissue-type plasminogen activator antigen. Tissue-type plasminogen activator antigen was determined with a commercially available enzyme-linked immunosorbent assay (Imulyse t-PA, Biopool). The assay detects free and complexed tissue-type plasminogen activator with similar efficiency. The intraassay and interassay variability was 6% and 9%, respectively.

Urokinase-type plasminogen activator and activatable single-chain urokinase activities. Urokinase-type plasminogen activator and activatable single-chain urokinase activities were determined by an immunoabsorbent activity assay (Chromolize u-PA, Biopool). The intraassay and interassay variability was 5% and 10%, respectively.

All these assays include the use of quenching and control antibodies to exclude falsely elevated results. Values represent the mean of duplicate measurements.

Statistical analyses. The Mann-Whitney U and Student t tests and correlation coefficient were used for statistical evaluations.

Results

The clinical data of the groups are shown in Table I. Preeclamptic women with IUGR were delivered earlier than the other groups. Two perinatal deaths were observed in that group.

The fibrinolytic parameters of the different groups are shown in Table II. When the fibrinolytic activators were evaluated, both activators, tissue-type and urokinase-type, increased in the third trimester of normal pregnancy in comparison with the levels observed in normal nonpregnant women (Table II). In relation to tissue-type plasminogen activator antigen levels, an increase was observed in preeclamptic groups with or without IUGR (18.1 ± 7.1 and 17.1 ± 13.5 ng/ml) as compared with normotensive pregnant groups with or without IUGR (8.4 ± 4.7 and 9.3 ± 3.5 ng/ml), respectively (Table II). The levels of the activatable single-chain urokinase plasminogen activator plus active uro-

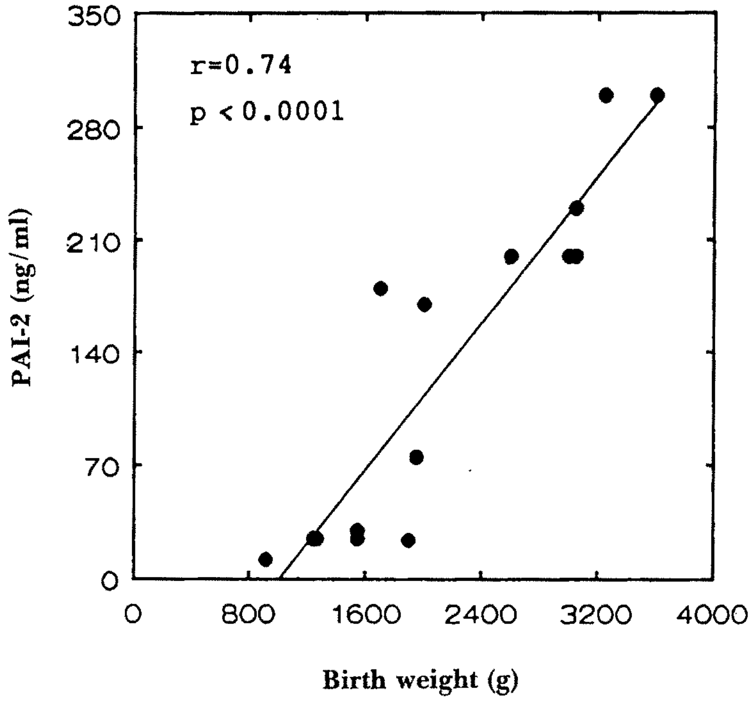

Fig. 1. Correlation between birth weight and plasminogen activator inhibitor type 2 *(PAI-2)* levels in intrauterine growth retardation and preeclampsia.

kinase plasminogen activator activities were lower in IUGR pregnancies, both normotensive and preeclamptic, than in the third trimester of normal pregnancy (matched controls).

The plasminogen activator inhibitor type 1 antigen and activity levels increased significantly in preeclamptic patients, with or without IUGR, in comparison with IUGR normotensive pregnancy or with the group of normal pregnant women (Table II).

In relation to the plasminogen activator inhibitor type 2 antigen levels, a significant decrease in the groups with IUGR was observed (118 ± 81 and 58 ± 64 ng/ml) in comparison with the groups without IUGR (238 ± 49 and 294 ± 93 ng/ml).

When the correlation between birth weight and different parameters was evaluated in the IUGR and preeclamptic groups, a significant correlation ($r = 0.74$, $p < 0.0001$) was observed between plasminogen activator inhibitor type 2 levels and fetal weight (Fig. 1). Moreover, the placental and fetal weight had a good correlation ($r = 0.63$, $p < 0.001$). No significant correlations, however, were obtained between birth weight and the other fibrinolytic parameters studied.

Comment

This study evaluates the fibrinolytic parameters in several groups: normal pregnancy, normotensive pregnancy complicated with IUGR, and preeclampsia with or without IUGR.

With respect to tissue-type plasminogen activator, we confirm previous reports showing that antigen levels increase in severe preeclampsia.[7, 15] Here we show an increase in tissue-type plasminogen activator antigen levels in severe preeclampsia, both with and without IUGR. This increase seems to be related to the activation of the hemostatic system and to the vascular alteration previously reported in preeclampsia.[3, 13, 15-18] In normotensive pregnancy complicated with IUGR, tissue-type plasminogen activator antigen levels are similar to those in matched controls.

The activatable single-chain urokinase plasminogen activator plus urokinase plasminogen activator activities decrease in both normotensive and preeclamptic IUGR groups, but in preeclamptic patients without IUGR no significant differences in the urokinase plasminogen activator levels in comparison with normal pregnancy were obtained. Since urokinase plasminogen activator activity increases during normal pregnancy, as described in a previous report,[19] the decrease in activity in pregnancies with IUGR could suggest that the levels correlate with placental function. However, no significant correlation ($r = 0.40$) was observed between urokinase plasminogen activator levels and fetal weight.

In relation to plasminogen activator inhibitors, an increase in type 1 antigen is observed in the two groups of women with preeclampsia with or without IUGR, in comparison with normal pregnancy. However, a decrease in type 2 antigen levels occurs in preeclampsia with IUGR and in normotensive pregnancies complicated with IUGR. Because plasminogen activator inhibitor type 2 is synthesized by the placenta[20] and localized in villous syncytiotrophoblasts,[21, 22] the decrease in the type 2 level in IUGR pregnancies can be due to the placental alteration observed in these pregnancies.[2, 3, 23]

The placenta is a source not only of type 2 plasminogen activator inhibitor but also of type 1, and type 1 has been found in the invading cytotrophoblasts of human placenta.[22] However, the levels of plasminogen activator inhibitor type 1 are increased in preeclamptic patients but similar in normotensive pregnancies with IUGR in comparison with normal pregnancies. The origin of type 1 can be multiple, from endothelium, activated platelets, or placental vasculature.[22, 24, 25] In preeclamptic patients alterations of endothelium, placenta, and hemostatic system have been described,[3, 13, 15-18] and this may increase, directly or indirectly, the levels of plasminogen activator inhibitor type 1 in severe preeclampsia. On the other hand, the high level of plasminogen activator inhibitor type 1 in severe preeclampsia would contribute to the persistence of fibrin in the uteroplacental vessels.[3]

We conclude that increased type 1 plasminogen activator inhibitor levels are associated with severe preeclampsia and that plasminogen activator inhibitor type 2 levels decrease in pregnancies with IUGR. Plasminogen activator inhibitor type 2 could be considered an adequate marker of placental function.

We thank Mrs Pilar Escamilla and Mrs Araceli Serralbo for their technical assistance.

Arterial blood flow velocity waveforms of the pelvis and lower extremities in normal and growth-retarded fetuses

Giancarlo Mari, MD
Houston, Texas, and New Haven, Connecticut

Serial measurements of femoral artery flow velocity waveforms were made at specified intervals of 3 to 4 weeks from 15 to 20 weeks of gestational age to 35 weeks and 1- to 3-week intervals thereafter until delivery in 12 normal fetuses (group 1A) with pulsed Doppler ultrasonography. The pulsatility index of the femoral artery increased linearly with advancing gestation in all 12 fetuses; this was associated with reverse diastolic flow velocity waveforms. In 30 other normal fetuses (group 1B) whose gestational ages ranged between 16 and 38 weeks (mean ± SD, 29.5 ± 5.6 weeks), the femoral artery flow velocity waveforms were analyzed with the external iliac artery, internal iliac artery, and umbilical artery waveforms. No significant difference was observed between the pulsatility index of the external iliac artery and that of the femoral artery (mean ± SD, 3.7 ± 1.1 vs 3.7 ± 1.1). The pulsatility index of the internal iliac artery was significantly higher than that observed in the umbilical artery (mean ± SD, 1.27 ± 0.28 vs 1.12 ± 0.23). The femoral and umbilical artery velocity waveforms also were determined in 20 fetuses with intrauterine growth retardation (group 2), whose gestational ages ranged between 24 and 36 weeks (mean ± SD, 31 ± 3.4 weeks). Abnormal femoral artery pulsatility index was recorded in two fetuses who died. Absent or reverse flow of the umbilical artery was recorded in 10 fetuses; four of them died, and four others manifested fetal distress or required admission to the neonatal intensive care unit or both. These preliminary data suggest that the femoral artery pulsatility index cannot be used as an indicator of adverse fetal outcome, whereas absent or reverse flow of the umbilical artery seems to be better correlated with adverse fetal outcome. (AM J OBSTET GYNECOL 1991;165:143-51.)

Key words: Femoral artery velocimetry, external iliac artery velocimetry, internal iliac artery velocimetry, pulsatility index, IUGR

Much of our knowledge of the circulation of the human fetus is derived from animal work, which has shown that distribution of the cardiac output to the kidneys is 1.8% to 2.9% during gestation, whereas the total carcass of the fetus receives a mean of 32% to 40% of the combined ventricular output; 16% is distributed to the lower carcass and 15% to 23% to the upper carcass.[1] It has been shown that there is a redistribution of the blood flow from the periphery to the brain during fetal hypoxemia in the lamb.[2] Therefore the peripheral circulation in the skin and muscles, which receives a large percentage of fetal cardiac output, is the site where vasomotor responses may affect major redistribution of the fetal circulation.

Pulsed Doppler ultrasonography represents a noninvasive method that allows examination of the cardiovascular system of the human fetus. Recently, combined Doppler studies have reported that hypoxemia in the fetal lamb is associated with abnormal femoral artery

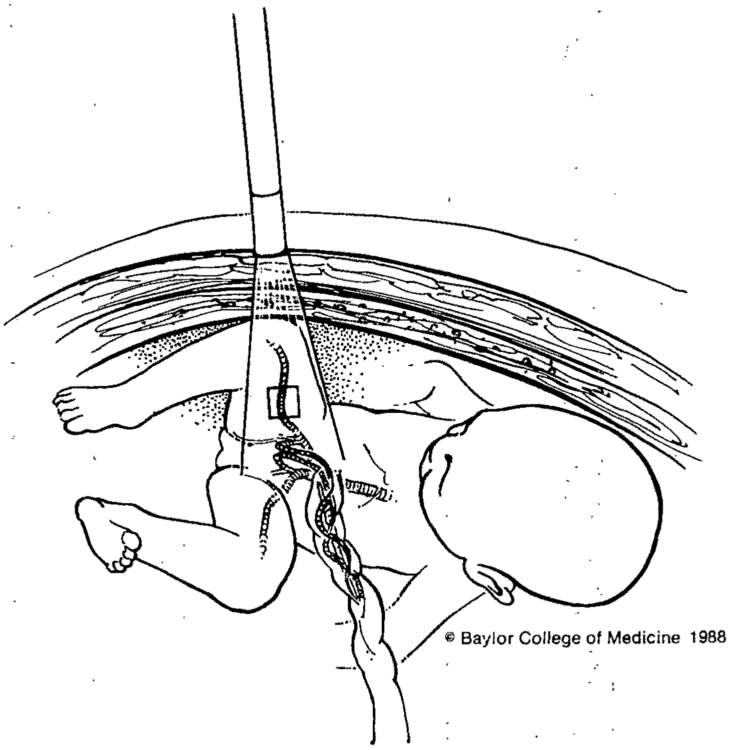

Fig. 2. Drawing showing ideal plane used in Doppler ultrasonographic studies of femoral artery.

flow velocity waveforms without appreciable effect on umbilical artery velocity waveforms.[3] Thus the study of the femoral artery with Doppler ultrasonography can provide information regarding the vascular resistance of the lower extremities and can also contribute to our understanding of the fetal circulation in normal fetuses and fetuses with intrauterine growth retardation (IUGR).

This communication introduces a pulsed Doppler method for recording flow velocity waveforms from the femoral artery, and the external and internal iliac arteries. The data obtained in 12 fetuses who were followed up longitudinally have permitted an evaluation of the variability of the femoral artery velocity waveforms during gestation and have provided the basis for the development of tables giving the normal variability as a function of gestational age. Furthermore, femoral and umbilical artery flow velocity waveforms obtained in 20 fetuses with IUGR are reported and compared with those obtained in normal fetuses.

Material and methods

This study was carried out with data collected from 42 normal fetuses (group 1) and 20 fetuses with IUGR (group 2) between May 1988 and February 1990. The patients of the two groups were primarily middle-class women from the Houston area. The patients of the first group were delivered of infants after 37 weeks' gestational age, and comprehensive pediatric assessment within 24 hours of delivery revealed no evidence of growth abnormalities or congenital anomalies. Birth characteristics such as weight, length, head circumference, and abdominal circumference were within the normal ranges for singletons determined by Usher and McLean.[4]

Fetal age determination. Fetal age determination for the fetuses of group 1 was based on the last menstrual period, which was confirmed by first-trimester and early second-trimester ultrasonographic examinations (crown-rump length, biparietal diameter, and femur diaphysis length measurement) in all of the fetuses. For the fetuses of group 2 gestational age was determined by both menstrual history and ultrasonographic assessment of fetal biometry either from a scan before 20 weeks' gestation or, if such a scan had not been performed, from the first ultrasonographic assessment in this study. Gestational age was based on the last menstrual period when it differed by <2 weeks from that determined by ultrasonographic parameters. Gestational age was based on the ultrasonographic assessment if the patient was unsure of her last menstrual period or if the discrepancy between last menstrual period and ultrasonographic gestational age was >2 weeks.

Fetal growth retardation was defined on the basis of ultrasonographic measurements of head and abdominal circumference >2 SD below the normal mean value for gestational age,[5] birth weight >2 SD below the normal mean value for gestational age,[4] decreased amniotic fluid volume,[6] and malnourished infant.[7] When three of these criteria were satisfied, the infant was categorized as having IUGR. The data obtained from the Doppler studies were not used in the clinical management of the patients.

Doppler examinations. Doppler examinations of the femoral artery in 12 fetuses of group 1 (group 1, A) were carried out at 3- to 4-week intervals from 15 to 20 weeks' gestational age (initial scan, mean ± SD, 17 ± 1.8 weeks) to 35 weeks and at 1- to 3-week intervals thereafter until delivery. To determine whether different arteries of the pelvis and lower extremities had a different pulsatility index value, the femoral artery flow velocity waveforms were analyzed with the external and internal iliac arteries and the umbilical artery on one occasion in 30 other normal fetuses between 16 and 38 weeks' gestation (mean ± SD, 29.5 ± 5.6 weeks). In the fetuses with IUGR (group 2) whose gestational ages ranged between 24 and 36 weeks (mean ± SD, 31 ± 3.4 weeks), the femoral artery and the umbilical artery were studied on one occasion.

A General Electric PASS II (General Electric Medical Systems, Milwaukee) dynamic image scanner was used. The 2.5 MHz transducer used a 2 mm sample volume. A pass filter between 0 and 50 Hz was used. Doppler ultrasonographic energy was 114 mW/cm^2 spatial peak temporal average intensity. The fetuses were examined with the mothers in a semirecumbent position. Doppler examination of the femoral artery was performed in the following sequence: After imaging of a longitudinal section of the thigh and pelvis in which the bladder could be visualized (Fig. 1), the sample volume was positioned on the femoral artery at the upper third of the thigh (Fig. 2), and Doppler waveforms of the femoral artery and vein were displayed on either side of the baseline (Fig. 3). When the femoral artery could not be visualized clearly, as shown in Fig. 1, the sample volume was positioned inside the pelvis, along the side of the bladder, where two different waveforms could be recorded at the same time, as reported previously.[8] This point corresponded to the bifurcation of the common iliac artery into the internal and external iliac arteries, as has been determined by following the common iliac artery to this point. The waveform at higher diastole corresponded to the internal iliac artery from which the umbilical artery takes its origin, whereas the waveforms at low diastole corresponded to the external iliac artery.[8] From the point at which the two waveforms were imaged, the sample volume was moved toward the thigh, which enabled the signal to be recorded at different levels along the external iliac artery until it left the pelvis and became the common femoral artery.

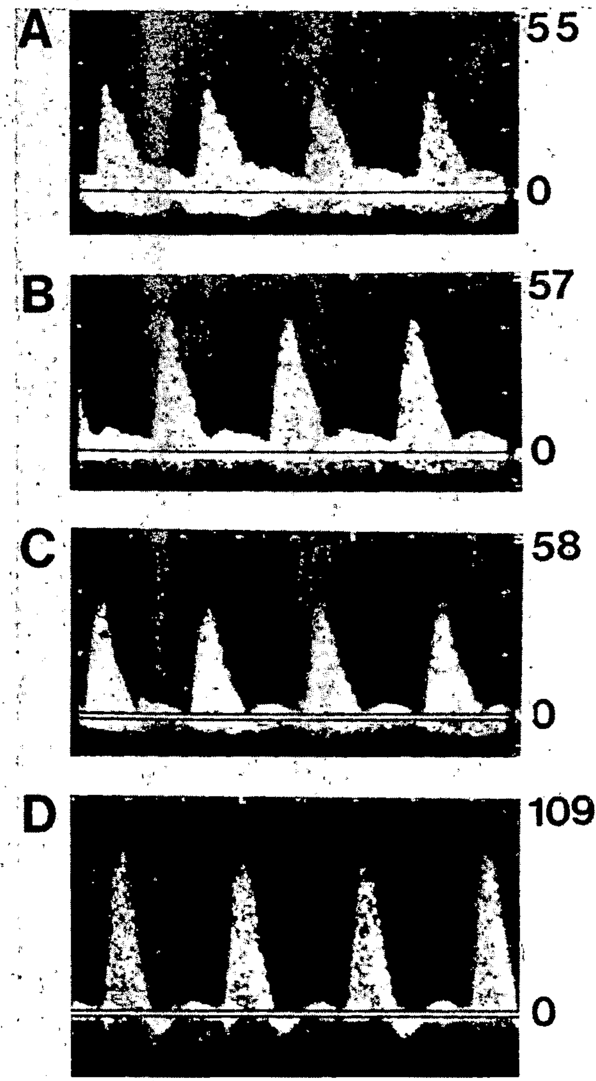

Fig. 3. Flow velocity waveforms from fetal femoral artery at 18 (A), 24 (B), 30 (C), and 39 weeks' gestation with forward diastolic flow in A, presence of notch in B and C, and reverse flow in D.

In 10 normal fetuses, two-dimensional directed pulsed Doppler waveforms (Acuson 128, Acuson Co., Mountain View, Calif.) were compared with pulsed Doppler waveforms with color-flow Doppler imaging (Acuson 128). Before the femoral artery was interrogated with pulsed Doppler ultrasonography, color-flow mapping was used to confirm that the sample volume had been positioned on the femoral artery.[8] Color Doppler was also used to distinguish anatomically the external and internal iliac arteries.

Data analysis. The Doppler velocity waveforms were recorded on videotape, and a digitized computer system (Digisonics Inc., Houston) was used to calculate the following variables: peak velocity, lowest diastolic velocity, and mean velocity. Three consecutive wave-

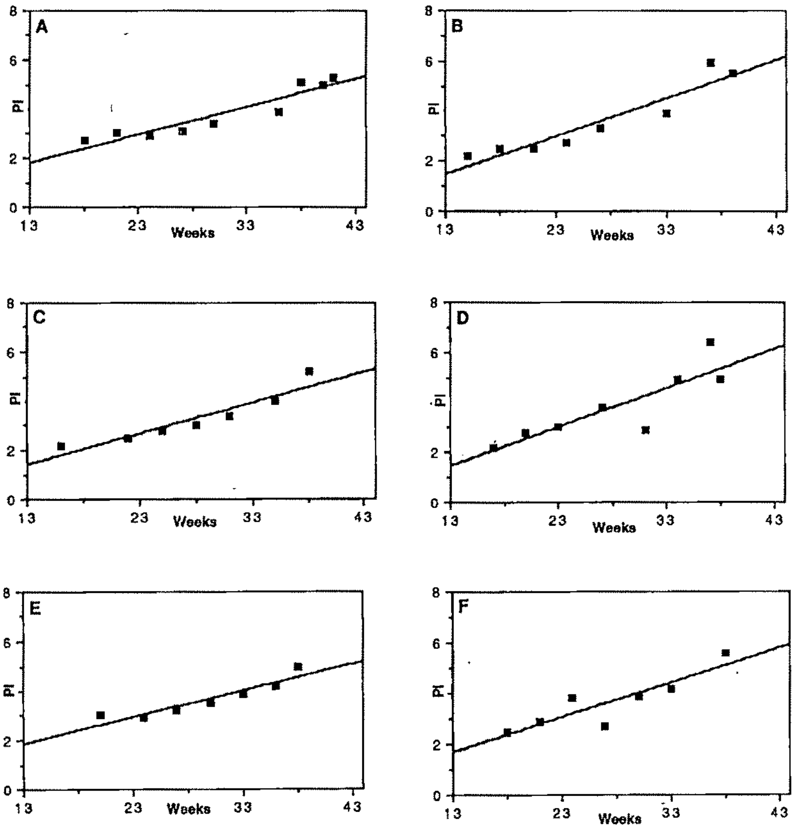

Fig. 4, ***A*** to ***F*.** Individual femoral artery pulsatility index values of six normal fetuses during gestation as determined from serial measurement.

forms were analyzed, and the results were averaged. The pulsatility index[9] [(Peak velocity − Lowest diastolic velocity)/Mean velocity] was then calculated. Measurements were obtained only during fetal apnea, which was defined as the absence of visible changes in the waveform patterns for at least 15 waveforms.

The intraobserver error (coefficient of variation) for the pulsatility index of the femoral artery was 7.7%, as has been reported previously.[8]

Changes in pulsatility index with gestational age for the fetuses of group 1, A, were characterized quantitatively by fitting mathematical functions to the experimental data. For each fetus regression analysis was used to compare the pulsatility index with gestational age. We looked for the optimal polynomial model on the basis of two criteria: coefficients different from zero and maximal coefficient of determination (R^2). Analysis of variance was used to determine if the regression accounted for a significant part of the variability in the dependent variable. A $p < 0.05$ was considered to indicate statistical significance. Corresponding coefficients for individual fetuses, as well as the R^2 values, were averaged, and their standard deviations were determined and used to construct tables giving the normal variability as a function of gestational age.

In the fetuses of group 1, B, analysis of variance and a multiple comparison test (Newman-Keuls test) were used for statistical analysis. A $p < 0.05$ was considered to indicate statistical significance.

The pulsatility index values for the IUGR fetuses (group 2) were compared with those of the normal fetuses (group 1, A). All analyses were performed on a Macintosh Plus computer with the Stat View statistical package (Albacus Concepts Inc., Berkeley, Calif.).

Results

The patients of group 1, A, were delivered of fetuses between 38 and 42 weeks' gestation (mean ± SD, 39.7 ± 1.2 weeks). Fetal femoral artery flow velocity waveforms in these fetuses were successfully obtained from 93 of the 106 examinations attempted (88%). Failure to obtain flow velocity waveforms was the result of fetal movements (especially before 30 weeks' gestation) and fetal breathing.

The pulsatility index increased linearly during gestation in all of the fetuses of group 1, A (Fig. 4, *A* to *F*, and Fig. 4, *G* to *L*); this was consistent with the presence of reverse flow in the diastolic component of the femoral artery waveform (Fig. 3) in the third trimester in those fetuses followed up longitudinally.

The table presents coefficients (a_0 and a_1) of linear model fitted to femoral artery pulsatility index measurements obtained serially at different gestational ages in 12 fetuses. R^2, Coefficient of determination.

Table I presents the coefficients of the linear model and the R^2 for each individual fetus. The changes in pulsatility index as a function of gestational age are presented in Table II. Analysis of variance indicated that the relationship to gestational age was statistically significant in these fetuses.

In nine fetuses followed up longitudinally, who were not included in our analysis because of preterm labor (n = 1), first pulsatility index measurement after 20 weeks' gestation (n = 5), hypertension (n = 2), or multicystic kidney (n = 1), the pulsatility index increased linearly and was associated with the presence of reverse

flow in the diastolic component of the femoral artery with advancing gestation.

In fetuses of group 1, B, analysis of variance indicated significant differences in the pulsatility index values of the four vessels studied (F = 91.327, $p < 0.0001$). The Newman-Keuls test revealed a significantly higher value for the pulsatility index in the internal iliac artery than in the umbilical artery (1.27 ± 0.28 vs 1.12 ± 0.23). The external iliac artery and the femoral artery did not show any significant difference (3.7 ± 1.1 vs 3.7 ± 1.1), and the external and femoral arteries showed a significantly higher value when compared with that of both the umbilical artery and the internal iliac artery.

The femoral artery pulsatility index of two fetuses with IUGR was higher than 2 SD for gestational age (Fig. 5). The umbilical artery pulsatility index was abnormal in 10 fetuses (with absent or reverse diastolic

flow velocity waveform); four of them died, and in four other fetuses either fetal distress developed or they were admitted to the neonatal intensive care unit or both (Tables III and IV).

Comment

A study by Stewart et al.[10] assessed the maximum velocity waveform in the external iliac artery. These authors stated that during normal pregnancy there is continuous forward flow throughout the cardiac cycle in the external iliac artery; this is associated with a decrease in pulsatility index of this artery. The same authors demonstrated that in fetuses with IUGR the pulsatility index of the external iliac artery increases, which suggests a redistribution of the blood flow from the lower extremities to the brain. These authors observed that the femoral artery would have been a more obvious choice for assessing lower-extremity blood flow. However, despite color-coded Doppler, they only rarely succeeded in identifying this vessel because of the related course of the femoral artery and femur, which often concealed the vessel from ultrasonographic inspection. In addition, they reported that the external and internal iliac arteries can be easily identified by color-flow mapping.

Our data show that flow velocity waveforms of the fetal femoral artery and the external and internal iliac arteries can be obtained by the pulsed Doppler system and color-flow mapping. In our experience it is easy to use color Doppler to visualize the internal iliac artery in all of the cases; however, it is more difficult to visualize the external iliac artery and the femoral artery in all of the cases. There are two reasons for this. The first is anatomic. In the fetus the internal iliac artery is twice as large as the external iliac artery.[11] The second reason concerns the characteristic waveforms. The internal iliac artery presents, as does the umbilical artery, continuous diastolic flow, whereas the external iliac artery and the femoral artery have low or reverse diastolic flow, which indicates intermittent flow toward the thigh and leg. With color Doppler it is possible to follow the internal iliac artery, which is positioned along the side of the bladder. This artery is directed downward; then it becomes anterior to the bladder and runs superiorly on the inner aspect of the anterior wall of the abdomen to reach the umbilicus and converges toward the same vessel from the opposite side. Having passed through the umbilical opening, the two arteries, which are now called *umbilical arteries*, enter the umbilical cord, become coiled around the umbilical vein, and ultimately ramify in the placenta.[11] Through the internal iliac artery passes the blood flow that is directed to the placenta, whereas the blood flow that is directed mainly to the lower extremities passes through the external iliac artery.

We have done a longitudinal study of the femoral artery velocity waveforms, and we found femoral artery reverse flow waveforms late during gestation in all of

§Fetal death.

the fetuses, as well as an increase of the pulsatility index of the fetal femoral artery with advancing gestation. We have not found a significant difference between the pulsatility index values of the external iliac artery and the femoral artery. When the vascular anatomy of the pelvis and thigh is considered, it is easy to understand why there is no difference in the waveforms of these two arteries. The external iliac artery extends from the bifurcation of the common iliac artery to a point beneath the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis. Entering the thigh below the inguinal ligament, the vessel becomes the femoral artery. The external iliac artery gives off few branches, the largest two of which are the inferior epigastric and the deep iliac circumflex.[11] The femoral artery and the external iliac artery differ only in location (inside the pelvis, external iliac artery; outside the pelvis, femoral artery).

Our results are the opposite of those reported by Stewart et al.[10] The pulsatility index values of the external iliac artery and the umbilical artery reported by those authors are quite similar. The only difference between the velocity waveforms of these two arteries is the higher pulsatility index value of the external iliac artery. Our study shows that the pulsatility index of the internal iliac artery is higher than that of the umbilical artery. This difference can be compared with the different umbilical artery pulsatility index values obtained at the level of the placenta and at the level of abdominal insertion.[12] The waveforms of the external iliac artery and internal iliac artery are completely different.[8] We have never seen external iliac artery waveforms such as those presented by Stewart et al.[10] The waveforms presented by those authors are similar to those of the umbilical artery and internal iliac artery.

The reverse flow, which appears in the third trimester in the fetal femoral artery flow velocity waveform, could be due to an increase of the resistance in the lower extremities, as Rittenhouse et al.[13] have shown in animal experiments. The blood flow at the level of the common iliac artery finds a high resistance in the external iliac artery, and therefore it is mainly directed toward the placenta; this is known to decrease the vascular resistance with advancing gestation.[14-16]

Our study shows that in 2 fetuses with IUGR, the pulsatility index of the fetal femoral artery was above the upper limit for gestational age. The two fetuses died; the first in utero, the second after 23 days of life. The femoral artery pulsatility index was normal in three other fetuses who died after delivery and in six other fetuses in whom fetal distress developed in labor or who were admitted to the neonatal intensive care unit or both. The absent or reverse diastolic velocity of the umbilical artery was associated with four fetal deaths and with four fetuses in whom fetal distress developed or who were admitted to the neonatal intensive care unit or both.

The clinical importance of our results is that reverse flow of the fetal femoral artery and external iliac artery is normal in the third trimester and is not associated with fetuses with IUGR and poor fetal outcome, as has been reported for the umbilical artery.[14] In addition, the study of the femoral artery does not seem to be a good indicator of adverse fetal outcome when compared with study of the umbilical artery, in which a correlation between abnormal waveforms and poor placental gas exchange has been reported.[17] Furthermore, more extensive studies are necessary.

We thank Dr. R.L. Deter, Dr. R.J. Carpenter, Dr. W. Gonsoulin, and Laura J. Bryson.

The influence of contamination of culture medium with hepatitis B virus on the outcome of in vitro fertilization pregnancies

**Helena C. van Os, MD,[a] Aat C. Drogendijk, PhD,[a] Willem P.F. Fetter, PhD,[b]
Rudolf A. Heijtink, PhD,[c] and Gerard H. Zeilmaker, PhD[d]**
Rotterdam, The Netherlands

Heat-inactivated human serum is added to the culture medium used for in vitro fertilization and other forms of assisted conception. Because one batch of pooled serum contained hepatitis B virus, an epidemic occurred among women participating in the treatment program. Seventy-nine women had serologic proof of hepatitis B infection. This incident gave the opportunity to study the effect of hepatitis B virus on pregnancy outcome and the newborn. The situation is unique because the preimplantation embryo was exposed to hepatitis B virus or the pregnancy was complicated by a (sub)clinical infection. Twenty-four women were or became pregnant while having an acute hepatitis B infection. Five pregnancies ended in abortion. The remaining 19 pregnancies ended in the birth of 24 children. No evidence for any harmful effect of exposure to hepatitis B virus in the embryonic or fetal period on the newborn could be found. (AM J OBSTET GYNECOL 1991;165:152-9.)

Key words: In vitro fertilization, hepatitis B infection, pregnancy outcome

Hepatitis B epidemics have occurred from time to time as a result of medical procedures such as vaccination,[1,2] acupuncture,[3] surgery,[4-7] or administration of red blood cells to elicite erythrocyte antibodies.[8] On March 2, 1988, a hepatitis B epidemic was discovered in women treated at our in vitro fertilization (IVF) center during the preceding months. During the IVF procedure, oocytes, spermatozoa, and, after fertilization, preembryos are kept in tissue culture medium containing 7.5% heat-inactivated human serum. The human serum for the tissue culture medium is usually obtained from the woman involved, but in special cases pooled serum from pregnant women is used. Because culture medium with pooled serum appeared to improve the results of IVF, pooled serum was also used in cases without specific indication for this approach.

In this study we describe a hepatitis B epidemic caused by a human serum pool contaminated with hepatitis B virus. The contaminated culture medium had been used from Nov. 2, 1987, until Jan. 21, 1988. In this period 175 couples (193 treatments) had been treated with IVF and embryo transfer, transfer of frozen-thawed preembryos or other forms of assisted conception (i.e., intrauterine insemination, direct intraperitoneal insemination, and gamete intrafallopian transfer). For transfer of frozen-thawed preembryos and for intrauterine insemination, direct intraperitoneal insemination, and gamete intrafallopian transfer treatment, only culture medium with 7.5% (vol/vol) pooled serum was used. The inoculation volume was about 50 μl of culture medium.

The effect of the hepatitis B infection on the course of pregnancy and the unborn child is described in this article.

Patients, pregnancies, and treatment

All couples involved were instructed to come as soon as possible to the outpatient department for blood sampling and passive and active immunization with anti-hepatitis B immunoglobulin (HBIG) (Central Laboratory of the Netherlands Red Cross Blood Transfusion Service, Amsterdam) and HBvax-DNA (Merck Sharp & Dohme, West Point, Pa.). All serum samples were tested for hepatitis B surface antigen (HBsAg) and for antibodies to hepatitis B core antigen by enzyme-linked immunosorbent assay. If these were present, supplementary tests for hepatitis B e antigen (HBeAg) and for antibodies to HBsAg (anti-HBs) and HBeAg (anti-HBe) were performed. The test results of this first screening indicated that the original period could be divided into two parts: Nov. 2 until Dec. 13, 1987 (period A)—use of culture medium containing hepatitis B virus (HBV) certain; Dec. 13, 1987, until Jan. 21,

1988 (period B)—use of culture medium containing HBV improbable, because none of the women treated in this period had signs of a hepatitis B infection (acute hepatitis B infection, seroconversion, or the presence of anti-HBc antibodies of the immunoglobulin M type. Unfortunately, we could not examine the original serum because all of it had been used for preparing the culture medium. Also, all of the contaminated culture medium was used, so we could not check that either.

An overview of all kinds of treatment is given in Table I.

The 166 IVF treatments resulted in 40 clinical pregnancies (a positive urine pregnancy test, detection level 50 IU/L, 17 days after ovum pickup). Nine of these pregnancies ended in clinical abortion between 7 and 14 weeks of amenorrhea; there was one ectopic pregnancy. Eight women who had a treatment not resulting in pregnancy in period A or B became pregnant after Jan. 21, 1988 (seven of these pregnancies were the result of IVF treatment; one woman conceived spontaneously). One of those seven IVF pregnancies ended in clinical abortion. Transfer of cryopreserved preembryos resulted in two clinical pregnancies, both of which ended in a clinical abortion. The intrauterine insemination, direct intraperitoneal insemination, and gamete intrafallopian transfer treatments did not result in pregnancy.

Table II shows the number of clinical IVF pregnancies and pregnancy outcome in periods A and B and the outcome of the above-mentioned seven pregnancies that occurred after Jan. 21, 1988, compared with a control period (January to October 1987). With the χ^2 test no significant differences in the percentage of pregnancy per embryo transfer ($p = 0.8$), percentage of abortion ($p = 0.8$), and percentage of multiple pregnancy ($p = 0.9$) could be found.

In period A the culture medium was prepared with pooled serum containing HBV. The preembryo was exposed to HBV by means of this "pool culture medium." The developing fetus could be exposed to the HBV if the mother suffered from a (sub)clinical hepatitis B infection as a result of contamination with the HBV at embryo transfer. In period B the pool culture medium probably was free of HBV. One of the women who conceived in this period also had been treated with IVF and embryo transfer in period A. She was still HBsAg negative at the time of the IVF treatment that resulted in the pregnancy, but was HBsAg positive for a short period of time during the first trimester (<13 weeks), so this fetus from period B could have been exposed to HBV at this later age. Of the eight women who were infected with HBV during IVF treatment in period A but became pregnant after Jan. 21, 1988, six were HBsAg positive at the time of conception, whereas two were already in the convalescent phase. The preembryos of the six women who were HBsAg positive at the time of conception were exposed to HBV when they were cultured in medium with 7.5% patient serum, while the developing fetus could be exposed to HBV because of the viremia of the mother.

Table I. Subdivision of 193 treatments performed in period A and period B

	Period A	*Period B*	*Total*
IVF and embryo transfer	116	50	166
Transfer of preembryos cryopreserved before Nov. 2, 1987	10	1	11
Transfer of preembryos cryopreserved between Nov. 2 and Dec. 13, 1987		2	2
Cryopreservation of preembryos*	8	1	9
Direct intraperitoneal insemination	1	2	3
Intrauterine insemination	1		1
Gamete intrafallopian transfer	1		1
TOTAL	137	56	193

*These preembryos were thawed and transferred after Jan. 21, 1988, but were potentially HBV contaminated by the pooled serum from period A or B.

At the first screening a blood sample was taken from all couples treated in the above-mentioned period and passive and active immunization (5 ml HBIG and 10 µg HBvax-DNA) administered to them. The results of the blood test (enzyme-linked immunosorbent assay) were known the next day. If the test showed serologic proof of a (cured) hepatitis B infection, the immunization was discontinued. The full immunization scheme consisted of 5 ml of HBIG in months 0 and 1 and 10 µg of HBvax-DNA in months 0, 1, 2, and 6.

To avoid needless immunization of pregnant women, their blood was checked with a rapid HBsAg test (Hepatest, Wellcome Laboratories, Dartford, England). If the test result was negative, the woman was immunized (Fig. 1). When the first screening was performed, 39 women knew they were pregnant; the duration of pregnancy varied between 4 and 19 weeks. Seven of them were slightly or severely icteric. With the rapid HBsAg test, 12 of the 39 pregnant women were found to be HBsAg positive, while the enzyme-linked immunosorbent assay showed that 14 of them were HBsAg positive (rapid HBsAg test = 12/14, 86% true positive; 2/14, 14% false negative). The two women who had a false-negative rapid HBsAg test had a very low titer of HBsAg in the enzyme-linked immunosorbent assay.

After the first screening two women were discovered to be pregnant. One of these pregnancies was the result of IVF treatment with embryo transfer on Feb. 28,

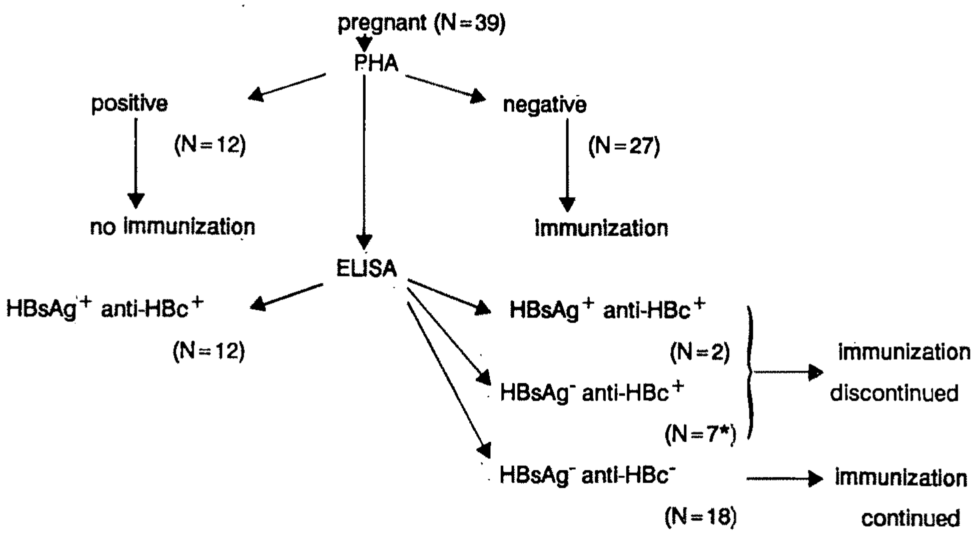

Fig. 1. Management of women who were pregnant at time of first screening. Immunization was started only if a rapid HBsAg test was negative. If enzyme-linked immunosorbent assay showed serologic proof of a (cured) hepatitis B infection, immunization was discontinued. *Asterisk,* One woman with positive preserum, serologic proof that she had recovered from past hepatitis B infection before IVF was started.

Table II. Total number of IVF pregnancies, percentage of clinical pregnancy per embryo transfer, number and percentage of abortions (including ectopic pregnancy), and multiple pregnancies in period A, in period B, after Jan. 21, 1988, and in a control period (January to October 1987)

	Total No. of IVF pregnancies	*Percentage of pregnancy per embryo transfer*	*Abortion*		*Multiple pregnancy**	
			No.	*%*	*No.*	*%*
Period A	26	22	7	27	5	26
Period B	14	28	3	21	2	18
After Jan. 21, 1988	7	23	1	14	2	33
Jan.-Oct. 1987	80	23	21	26	14	23

χ^2 Test: For percentage of pregnancy per embryo transfer, $p = 0.8$; for percentage of abortion, $p = 0.8$; for percentage of multiple pregnancy, $p = 0.9$ (no significant differences).

*Percentage of multiple pregnancies in all ongoing pregnancies.

1988, whereas the other one occurred spontaneously. Four pregnancies ended in clinical abortion after the first screening. Two of them were viable pregnancies (fetal heartbeats had been visualized with ultrasonography) and the remaining were blighted ova.

Table III represents the relationship between pregnancy outcome and the immunization scheme followed.

The course of pregnancy in women with and without serologic signs of HBV infection is shown in Table IV. No significant differences for percentage abortions ($p = 0.5$) or percentage multiple pregnancy ($p = 0.9$) could be found with the Fisher exact test.

According to the amount of HBV that was introduced into the uterine cavity three categories could be distinguished: category 1, the preembryo was cultured in the contaminated medium and about 50 μl of contaminated medium was used for transfer of the preembryos into the uterine cavity; category 2, the preembryos were cultured in the contaminated medium but were transferred into the uterine cavity in medium free of HBV; category 3, the contaminated medium was used for neither embryo culture nor embryo transfer, and the only contact with the HBV was by means of the glass capillary used to remove the cumulus cells from the oocyte. Of the couples treated with IVF between Nov. 2 and Dec. 13 (period A) only 86 could be classified with certainty into one of these categories.

In Table V the number and percentage of pregnancies in each category are shown. The figures indicate that contact with HBV during IVF treatment had no influence on the pregnancy rate or the course of pregnancy. There are no significant differences, except for the percentage of HBV infections (χ^2 test for trend, $p < 0.001$).

Table III. Potentially HBV-infected IVF pregnancies and administration of HBIG and HBvax-DNA

Fisher's exact test: For percentage of abortion, $p = 0.5$; for percentage of multiple pregnancy, $p = 0.9$ (no significant differences).
*Ectopic pregnancy included.
†Percentage of multiple pregnancies among all pregnancies beyond first trimester.

There were 79 women with proved hepatitis B infection. Two of them already were in the convalescent phase when they became pregnant, and 24 women were pregnant and 55 were not during the infection. Seven of the pregnant women (29.2%) were slightly or severely icteric, and seven (29.2%) complained about arthralgia, whereas two (8.3%) were HBsAg positive for a long period of time. In the nonpregnant group, 24 (43.6%) were icteric, 35 (63.6%) complained about arthralgia, and two (3.6%) developed an HBV carrier state.

Prenatal diagnosis. Amniocentesis or biopsy of the chorion villi because of advanced maternal age (≥36 years) was performed in six women. With one exception, all were HBsAg negative at the time of prenatal diagnosis. The amniotic fluid of the woman who had amniocentesis performed while she was HBsAg and HBeAg positive was weakly HBsAg positive. Contamination with blood of the mother is the most likely explanation for this finding.

Incidents during pregnancy. As far as the course of pregnancy is concerned, three pregnancies need to be discussed.

Case 1. Routine ultrasonographic examination in the twenty-fourth week of pregnancy showed fetal ascites. An extended echoscopic evaluation showed that the child had not only ascites but a ventricular septum defect as well. There also was a polyhydramnion. The ascites spontaneously disappeared, and in the thirty-first week of pregnancy it could no longer be detected. By that time, however, multiple intraabdominal calcifications of unknown origin were seen. At 36.6 weeks' gestation a cesarean section was performed because of dysmaturity of the child. At birth no abnormalities other than dysmaturity (birth weight of the girl, 1785 gm) could be found. Prenatal closure of the ventricular septum defect was presumed. The mother was in the eighteenth week of pregnancy at the time of the first screening. At that time she was HBsAg positive, but she became HBsAg negative when she was 22 weeks pregnant.

Case 2. This was a triplet pregnancy that, with the exception of jaundice of the mother, was more or less uncomplicated until the twenty-ninth week. One of the children died in utero without obvious cause. The pregnancy continued as a twin pregnancy, and at the end of the thirty-sixth week two healthy children (a boy and a girl) were born. The mother was HBsAg positive at the time of conception and remained HBsAg positive until about 1.5 weeks before delivery.

Case 3. This was a singleton pregnancy that, with the exception of jaundice of the mother, was uncomplicated until the twenty-sixth week. By that time the woman was admitted to the hospital because premature rupture of the membranes was suspected. There also were premature uterine contractions and some vaginal bleeding. Bed rest and tocolytics managed to stabilize the condition. She was dismissed 3 weeks later. At the end of the thirty-seventh week, a healthy son was born. The mother was HBsAg positive at the time of conception and remained HBsAg positive until the twenty-second week.

Management at birth. The gynecologist who performed the prenatal controls was instructed about man-

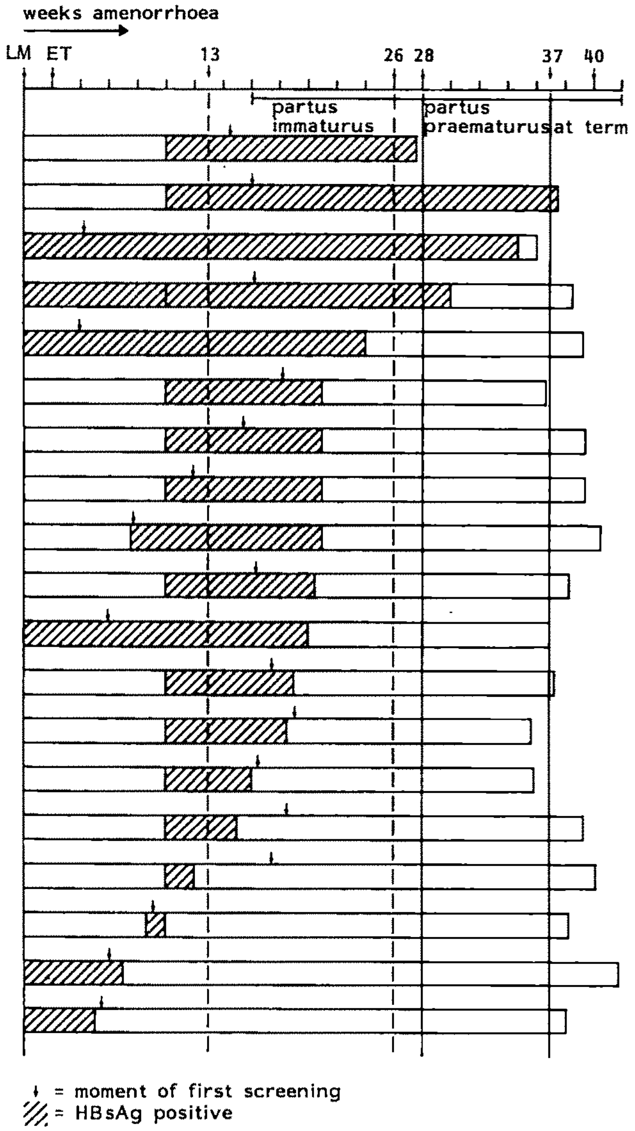

Fig. 2. Pregnancies with HBsAg-positive phase. Each *bar* represents a pregnancy, whereas HBsAg-positive phase is represented by *shaded* part. *Arrow,* Moment of first screening; *dotted lines,* end of first and second trimesters; *solid lines,* end period of immature and premature birth.

agement at birth. This consisted of (1) collecting 10 ml amniotic fluid, 10 ml of blood from the mother, and 20 ml of blood from the umbilical cord before delivery of the placenta, (2) administration of 250 IU HBIG to neonates of mothers who were HBsAg positive during the last 3 months of pregnancy or at the time of delivery, and (3) the scheme of follow-up by the pediatrician.

The babies were born between June 7 and Nov. 28, 1988. Duration of pregnancy varied between 27.6 and 41.6 weeks, and birth weight varied between 1075 and 4250 gm. Fig. 2 shows the period of pregnancy in which the women were HBsAg positive. Fourteen women were HBsAg negative at the time of conception but became contaminated during embryo transfer. The length of the incubation time of HBV infection is classically considered to range from 60 to 160 days.[9] Virus dose and inoculation route determine the incubation time.[10] After parenteral exposure, most cases of hepatitis appear during the first 50 to 60 days. Therefore the women were assumed to be HBsAg positive from the eighth week after embryo transfer. Five women were HBsAg positive at the time of conception. They also had been treated in period A but became pregnant after Jan. 21, 1988.

Two women were highly infectious (HBsAg and HBeAg positive) at the time of delivery. Two women were HBsAg negative at the time of delivery but HBsAg positive in the preceding 3 months. The eight children of these four women each received 250 IU HBIG within 2 hours of birth.[11, 12] Eleven women became HBsAg negative before the end of the second trimester and four before the end of the first. The hepatitis B infection had been cured at the time of conception in three women. Fifteen women had no sign of hepatitis B infection at all; six of them had been treated in period A and nine in period B.

One pregnancy (a triplet) ended in a partus immaturus (27.6 weeks). Fourteen children (one set of triplets, four sets of twins, and three singletons) were born before the end of the thirty-seventh week of pregnancy. The remaining 30 children (two sets of twins and 26 singletons) were born at term. In Table VI the number of immature, premature, and term births, and the number of children are shown in relation to hepatitis B infection of the mother during or before pregnancy. No significant differences between women with and without hepatitis B infection in percentage of immature, premature, and term births were detected.

Umbilical cord blood. Of the four children (immature triplet and term singleton) of the two women who were HBsAg and HBeAg positive at the time of delivery, the test results of the umbilical cord blood indicated the presence of HBsAg in three samples. Blood samples taken from these children some days post partum were HBsAg negative, so a perinatal hepatitis B infection in these children is very unlikely. Of the other 43 children, the test results of the umbilical cord blood were: HBsAg negative, anti-HBc negative, and anti-HBs positive in 20 cases; HBsAg negative, anti-HBc positive, and anti-HBs negative in two cases; and HBsAg negative, anti-HBc positive, and anti-HBs positive in 21 cases. The test results of umbilical cord blood and maternal blood were identical, indicating a passive diffusion of the anti-HBc and anti-HBs antibodies.

Perinatal death. Of the 49 children, 47 were born alive (25 girls, 22 boys). Of the immaturely born set of triplets (3 boys), one died 12 days post partum from septic candidiasis. Their mother was HBsAg and HBeAg positive at the time of delivery.

Two children were stillborn. One (a boy) was part of

χ^2 Test for percentage births, $p = 0.6$.

a triplet. He died in utero in the twenty-ninth week of pregnancy (see Incidents during pregnancy, case 2). The other one was part of a twin. The blood test of the mother indicated that she had a cured hepatitis B infection before she underwent IVF. At term, a healthy baby girl was born. The stillborn child had an extremely low birth weight, so it probably died in utero some weeks earlier.

Postnatal problems. Congenital malformation was not noticed in any of the children at birth. One boy, the youngest of the prematurely born triplet, was admitted to the hospital at the age of 6 weeks with a meningococcal meningitis. The pregnancy was the result of treatment in period A, contact of the preembryos with the HBV-containing culture medium was unlikely, and the mother had no signs of hepatitis B infection during pregnancy or after delivery. Another boy (born at term) was admitted to the hospital at the age of 2 weeks. He was suspected to have a sepsis, but a causative microorganism could not be found. The pregnancy was the result of treatment in period A, and the mother was 17.4 weeks pregnant when the hepatitis B epidemic was discovered. At the first screening her blood showed the serologic signs of a recently cured hepatitis B infection. The amount of anti-HBs indicated that she probably lost the HBsAg before the end of the first trimester. One girl (part of a prematurely born twin) was treated for cystitis. The pregnancy was the result of treatment in period A. At the time of first screening the mother was a little more than 19 weeks pregnant and had already entered the early recovery phase (HBsAg negative, anti-HBc positive, and anti-HBs negative). Another prematurely born girl (for details about the pregnancy see Incidents during pregnancy, case 1) was treated for otitis media. Three children (twins born at term and a girl born at term) had exanthema subitum. The mother of the twins was HBsAg positive at the time of conception but became HBsAg negative before the sixth week of pregnancy, while the mother of the other child already was in the recovery phase at the time of conception. Both pregnancies were the result of IVF treatment after Jan. 21, 1988. Two children (a boy and a girl both born at term) had cow's milk protein intolerance. One pregnancy was the result of treatment in period A. The mother was >18 weeks pregnant and already in the recovery phase at the time of the first screening. The other pregnancy was the result of treatment in period B. The mother received the full vaccination scheme.

Comment

Our main knowledge about the effect of the hepatitis B virus on the course of pregnancy and the unborn child stems from pregnancies in women who are HBV carriers or suffer from an acute hepatitis B infection during pregnancy.[13] When a woman is HBsAg positive at the time of conception, the oocyte can be exposed to the virus during ovulation and the preembryo while passing through the fallopian tube. It is presumed that the fetal organs become susceptible to HBV only in the third trimester. So, if the mother is HBsAg positive in the third trimester of pregnancy, there is a chance of prenatal infection. Placental leakages are thought to play an important role in HBV infections in utero.[14]

Children of women who are HBsAg positive at the time of birth, especially if they are also HBeAg positive, have a considerable chance of perinatal contamination.[15-17] The chances of becoming an HBV carrier are inversely correlated with age at the time of exposure to the virus.[18-20] To protect the newborn from neonatal HBV infection or from becoming an HBV carrier, the baby should be immunized immediately after birth.

A deficient clinical and laboratory protocol, together with insufficient instruction of the laboratory staff about the resistance of HBV to serum inactivation (30 minutes at 56° C), has led to the accidental infection described in this article.

The HBV contamination of IVF culture medium offered the opportunity to study the effect of exposure of a preembryo or fetus to the virus on pregnancy outcome but also pointed out the risk of using pooled serum. Contamination can be prevented by using only the patients' blood for preparing the culture medium. When use of donor serum is necessary, one should use the serum of a thoroughly screened (HBV and human immunodeficiency virus) female donor with proved fertility or fetal cord blood. A safe alternative is the use of human albumin solution or other serum substitutes. Much research is being done to find a substitute that is compatible with human serum.

The HBV exposure of the preembryo during IVF procedure did not result in any demonstrable damage, as may be concluded from the pregnancy rate per embryo transfer, the multiple pregnancy rate, and the rate of first-trimester abortion. The rates do not differ from those in periods without HBV contamination of the culture medium (Table II). Even if the preembryos were exposed to a relatively high dose of HBV, no negative effect on treatment and pregnancy outcome could be found, but the numbers are too low to allow a firm conclusion (Table V).

Likewise, the occurrence of a maternal hepatitis B infection during pregnancy did not seem to harm the embryo or developing fetus. In mothers with hepatitis B infection during pregnancy, the rate of multiple pregnancy, first-trimester abortion, immature birth, and premature birth did not differ significantly from those in mothers without hepatitis B infection during their pregnancy (Tables IV and VI).

In our observations there is no evidence for any harmful effect on fetus or newborn of either the exposure to HBV in the embryonic period or the occurrence of a maternal HBV infection during the first, second, or third trimester of pregnancy. In none of the total of 47 children born alive could a congenital HBV infection or a congenital malformation that could be related to HBV infection be demonstrated. In three children whose mothers were HBsAg and HBeAg positive at the time of delivery, the umbilical cord blood was HBsAg positive. In all three cases a blood sample taken some days post partum was HBsAg negative. It may be concluded that the umbilical cord blood of those children was contaminated with maternal HBsAg–positive blood. The intrauterine deaths of two children and the death of another child 12 days post partum were due to causes other than HBV infection. The same can be said of the children who became ill in the neonatal period. The clinical sepsis could not be explained by actual HBV infection, but some immunologic weakness resulting from HBV infection in the embryonic or fetal period cannot be excluded with certainty.

Theoretically, the absence of demonstrable or sustained presence of HBsAg in the neonatal blood does not prove that the HBV has not entered the fetal body early in pregnancy. Incorporation of (part of) the HBV deoxyribonucleic acid in the deoxyribonucleic acid of the fetal cells can be hypothesized to occur without a trace of HBsAg in the fetal blood or later in the neonatal blood. Tests to prove or deny this hypothesis, using molecular hybridization, are planned but not yet performed.

A long period of follow-up is needed, because problems relating to small defects may show themselves months to years after birth. Nevertheless, presently (11 to 15 months after birth) the observations on IVF offspring at risk of HBV influence are reassuring.

Early detection of preeclampsia

G.A. Dekker, MD, PhD,[a] and Baha M. Sibai, MD[b]
Amsterdam, The Netherlands, and Memphis, Tennessee

The signs and symptoms of preeclampsia are usually apparent at a relatively late stage in pregnancy (late second to early third trimester). However, the disorder results from abnormal interaction between fetal and maternal tissue much earlier in pregnancy, between 8 and 18 weeks' gestation. During the past two decades numerous clinical, biophysical, and biochemical tests have been proposed for the early detection of preeclampsia. Some of these tests are simple, whereas others are invasive; some have been studied extensively, while others are still under clinical investigation. A review of the literature indicates considerable disagreement regarding the sensitivity and predictive values of the various tests studied. The reported differences in the predictive values of these tests may be attributed to one or more of the following: populations studied, definition and prevalence of the disorder, techniques and methodology used in performing these tests, etc. As a result, there is disagreement regarding the ideal screening test to be used for identifying patients for clinical trials dealing with prevention of the disorder. (AM J OBSTET GYNECOL 1991;165:160-72.)

Key words: Preeclampsia, prediction, biophysical tests, biochemical tests

Preeclampsia is a common disorder of pregnancy and a major cause of maternal, fetal, and neonatal mortality and morbidity.[1-4] Thus its prevention would have a significant impact on maternal and perinatal outcome worldwide. Prevention not only requires knowledge of pathophysiologic mechanisms of disease, but also availability of methods of early detection, and means for intervention and correction of pathophysiologic changes.[5]

The signs and symptoms of preeclampsia become apparent at a relatively late stage in pregnancy, usually in the third trimester. However, the underlying cause of the pathophysiologic mechanisms that are thought to be responsible for the disease process appear to occur much earlier in pregnancy, between 8 and 18 weeks' gestation.[6] For that reason it seems logical to search for earlier indicators of this disorder,[7] and, indeed, a multitude of tests have been proposed as a means of predicting the later development of the disease (Table I). In reviewing the extensive literature on this subject one is faced with two major problems. One of these is the inconsistency in the terminology used to define or diagnose preeclampsia. Thus, for the purpose of this review, the term *preeclampsia* will be used to describe previously normotensive patients with persistent elevations in blood pressure appearing in the second half of pregnancy. The second major problem is the absence of internationally accepted criteria to judge the usefulness of a predictive test. Of course, the ideal predictive test should be simple and easy to perform early in pregnancy and be reproducible and noninvasive, with high sensitivity and a high positive predictive value. However, at this moment there is no one test that fulfills all the above criteria. In view of this, the actual value of an individual test used for early prediction of preeclampsia should be evaluated in the context of the clinical or research setting in which that particular test is used. For example, detailed longitudinal pathophysiologic studies, which may carry an appreciable burden for the study subjects, are possible only in rather small groups of high-risk patients selected by a test with a high predictive value. In this setting it is of lesser importance if the particular test is invasive, is time-consuming, or has only a moderate sensitivity. On the other hand, for a test to identify a large, high-risk group suitable for studying the effects of therapeutic intervention, the test needs to be inexpensive, easy to carry out, and noninvasive and express a high sensitivity. In these circumstances an average predictive value is acceptable.

In this review the various clinical, biochemical and biophysical tests that have been proposed to predict the development of this disease will be described, and their relative importance evaluated.

Standard methods of antenatal care

Antenatal visits are conventionally arranged monthly between 20 and 28 weeks, biweekly up to 36 weeks, and weekly thereafter until delivery. These visits are dominated by a check of blood pressure and urine and by the determination of weight gain. The issue of whether the development of preeclampsia may be predicted on the basis of these standard variables has been addressed in several retrospective and some prospective studies.[8-19]

Blood pressure. A large prospective study in 808 nulliparous and 175 parous pregnant women was reported by Moutquin et al.[9] The investigators used an automatic oscillometric sphygmomanometer and started their blood pressure readings between 9 and 12 weeks' gestation. A total of 7800 blood pressure readings were obtained at 4-week intervals. Among 734 initially normotensive nulliparous women, preeclampsia (blood pressure $>135/85$ mm Hg, edema, or proteinuria after 20 weeks) developed in 46 (6.3%). The sensitivity for predicting preeclampsia early in pregnancy (9 to 20 weeks) on the basis of the occurrence of a diastolic blood pressure of ≥ 80 mm Hg was 32% to 46%; on the basis of ≥ 85 mm Hg it was 16% to 31%, with specificities of 84% to 91% and 93% to 97%, respectively. The data revealed that a majority of pregnant women who remained normotensive during pregnancy had a diastolic blood pressure of ≤ 75 mm Hg before 20 weeks' gestation. The sensitivity of using an 80 to 85 mm Hg diastolic blood pressure level in the first half of pregnancy as a test for the later occurrence of preeclampsia was poor. The predictive value of a positive test was on the order of 20% to 30%, but the predictive value of a negative test was approximately 95%.

Values of mean arterial pressure in the second trimester (18 to 26 weeks) have been used in predicting the development of preeclampsia later in pregnancy. Page and Christianson[10,11] presented data on the outcome of pregnancy on the basis of a prospective study of 14,833 single births. They found that when the average mean arterial pressure (MAP) in the midtrimester was ≥ 90 mm Hg there was a significant increase in the frequency of preeclampsia, fetal growth retardation, and stillbirths. On this basis, an average MAP value of 85 or 90 mm Hg in the second trimester has been used by several investigators to predict the later occurrence of preeclampsia.

The reports from which sufficient information could be obtained to calculate statistics for the test results are summarized in Table II.[9-19] Only one group of authors[14] stated that the results of second-trimester MAP measurements were withheld from the physicians and the patients. In addition, the definition of preeclampsia shows significant inconsistencies. It is usually not stated whether elevations of blood pressure occurring for the first time during labor or in the early postpartum period are included; in most studies proteinuric preeclampsia is not distinguished from transient hypertension. An exception is the carefully conducted study reported by Villar and Sibai.[17]

Table I. Tests proposed for early detection of pregnancy-induced hypertensive disease

1. Standard methods of antenatal care
    - Blood pressure increase
    - MAP in second trimester
    - Proteinuria by dipstick, microalbuminuria
    - Excessive weight gain, edema
2. Vasoconstriction tests
    - Cold pressor test
    - Flicker fusion test
    - Isometric exercise test
    - Peripheral venous tone test
    - Roll-over test
    - Infusion of catecholamines, vasopressin
    - Infusion of angiotensin II
3. Biochemical markers
    - Uric acid
    - Urinary calcium excretion
    - Urinary excretion of tubular enzymes
    - Urinary excretion of prostacyclin metabolites
    - Placental proteins
    - Various enzymes
    - Platelet angiotensin II receptors
    - Platelet calcium response to arginine vasopressin
    - Clearance of dehydroisoandrosterone sulfate
4. Hematologic markers
    - Plasma volume, hematocrit, hemoglobin
    - Plasma factor VIII–related antigen activity
    - Ratio of factor VIII–coagulant factor VIII
    - Antithrombin III levels
    - Thrombin–antithrombin III levels
    - Protein C
    - Plasminogen activator inhibitor 1
    - Fibronectin, ED1 + fibronectin
    - Platelet count, platelet volume
    - β-Thromboglobulin, platelet factor IV
5. Ultrasonographic evaluation
    - Doppler waveforms of uteroplacental circulation
    - Placental location

Villar and Sibai[17] studied 700 young, normotensive, primigravid women prospectively during pregnancy. In this study a second-trimester MAP of >90 mm Hg had a sensitivity of 8% and a positive predictive value of 23% (incidence of preeclampsia, 19.6%). The respective values for a threshold increase of >15 mm Hg in diastolic pressure were 39% and 32%. For a threshold increase of >30 mm Hg in systolic pressure, values were 22% and 33%. They concluded that neither a second-trimester MAP >90 mm Hg nor a threshold increase in systolic or diastolic pressure during the third trimester was significantly predictive of the development of preeclampsia.

The general impression is that a pregnant woman with a diastolic blood pressure of ≤ 70 mm Hg, or a mean arterial pressure of about ≤ 80 mm Hg in the

*The data of Friedman and Neff are for maximal second-trimester MAP.

second trimester runs a small risk of having preeclampsia later in pregnancy. The consequences of this rather obvious conclusion for antenatal care are minimal. The final conclusion is, as already stated by Chesley and Sibai,[19] that if an increased second-trimester MAP level predicts anything, it is transient hypertension rather than preeclampsia-eclampsia.

Proteinuria. In a recent investigation of 100 pregnant women with mixed parity attending an antenatal clinic for high-risk patients, Lopez-Espinoza et al.[20] studied microalbuminuria using a sensitive radioimmunoassay to determine whether an increasing loss of albumin would predict the occurrence of proteinuric preeclampsia. No evidence was found that gross proteinuria is preceded by a gradual increase in microalbuminuria. In another recent investigation of 88 normotensive pregnant women with mixed parity (11.4% incidence of preeclampsia), a urine albumin concentration of ≥11 μg/ml was reported to have a sensitivity of 50% and a specificity of 82%, a positive predictive value of 26%, and a negative predictive value of 93%.[21] The general conclusion is that there is little value in using precise techniques of detecting proteinuria to predict preeclampsia.[22-24]

Weight gain. In 1952 Hamlin[25] made the rather dogmatic statment that "if a young primipara with a low initial blood pressure increases her weight by more than 8 lbs. between the 20th and 30th week, she will proceed almost inexorably towards eclampsia." This led to renewed and vigorous manipulation of the diets of millions of pregnant women. Hamlin's statements were checked in a careful retrospective study in 1457 selected primigravid women in Aberdeen.[26] About two thirds of the normotensive women and three fourths of the women in whom preeclampsia developed gained more than 8 pounds between 20 and 30 weeks of pregnancy. The authors concluded that the relationship of weight gain between 20 and 30 weeks of pregnancy to preeclampsia is too indefinite to be of any practical value in predicting the development of preeclampsia. This conclusion was later supported by the results of another retrospective study, also from Abderdeen.[27] In conclusion, there appears to be such an important variability in physiologic weight gain in pregnancy and such an overlap between weight gains of normotensive and hypertensive pregnant populations that weight gain cannot be used to predict the development of preeclampsia.[28-30]

Biochemical and biophysical tests of vasoconstriction. A variety of tests have been devised to demonstrate the presence or absence of an abnormal vascular responsiveness before the clinical onset of the disorder (Table I). Most of these tests have only historic value and will be mentioned only briefly.

Isometric exercise test. Isometric hand-grip exercise is known to increase systemic arterial blood pressure, presumably resulting from increased systemic vascular resistance.[31] For this reason, Degani et al.[32] proposed that the diastolic blood pressure response to an isometric hand-grip exercise test might reflect vascular reactivity in pregnant women and thus might be used to detect vascular hyperreactivity and to predict preeclampsia.

One hundred healthy primigravid women were subjected to an isometric hand-grip exercise test between 28 and 32 weeks' gestation.[32] Each woman was placed in the left lateral position, and blood pressure was recorded at regular intervals until it remained stable. Blood pressure measurements were taken on the passive arm, and an increase in the diastolic pressure of ≥20 mm Hg was taken as a positive isometric pressor response. The results of the test were not made available to the physicians taking care of these women or making the clinical diagnosis. Eighty-four women had a negative test (preeclampsia developed in three of them) and 16 had a positive test (three remained normotensive). These results gave a sensitivity of 81% and

*Main blood pressure criteria for diagnosis of preeclampsia: increase in diastolic blood pressure of ≥20 mm Hg and/or diastolic blood pressure ≥140/90 mm Hg.

†Pressor response 9 mm Hg defining a positive test. Pressor response 20 mm Hg = sensitivity of 0% and positive predictive value of 0%.

specificity of 96%. The positive predictive value was 81%, and the negative predictive value was 93%, with an incidence of preeclampsia of 16%.

Marya et al.[18] also reported on the predictive value of the isometric exercise test. They studied 200 women with mixed parity. Sensitivity of the test was reported to be 54%, specificity 98%, positive preditive value 79%, and negative predictive value 93% (incidence of preeclampsia, 14%). However, the authors did not report the definitions that were used for diagnosing preeclampsia. In conclusion, judgment on the isometric exercise test as a predictor of preeclampsia awaits the results of further carefully conducted prospective studies to support or refute its validity.

Roll-over test. The roll-over or supine pressor test was first described by Gant et al.[33] The test is performed between 28 and 32 weeks of pregnancy with the woman lying on her left side until the diastolic blood pressure, measured in the uppermost right arm, is stable. The woman is then turned on her back, and diastolic blood pressure is again recorded. A rise in diastolic blood pressure of ≥20 mm Hg defines a positive test. The first study comprised 50 randomly selected, healthy primigravid women. Pregnancy outcome was given for only 38 of the 50 women; apparently 12 had not completed their pregnancies when the report was published. Of 16 women with a positive roll-over test, pregnancy-induced hypertension developed in 15; of 22 women with a negative roll-over test, 20 remained normotensive. The prevalence of preeclampsia in this unselected sample of primigravid women was 44.7%. Since this original report, many reports have been published on this subject, which included >1500 patients.[7, 18, 20, 34-51] Results of pertinent studies are summarized in Table III. The sensitivity and specificity values of about 90% that can be calculated from the results of Gant et al.[34] were not confirmed in the majority of the other studies. Various factors may explain the marked disparity in results of a relatively simple test as the roll-over test. Although all investigators define an increase in diastolic blood pressure of ≥20 mm Hg as a positive test, there was considerable variation among investigators in the method of the test[15] and the measurement of blood pressure (using Korotkoff phase 4, phase 5, or Doppler-shift signals). In addition, there were the usual inconsistencies in the definition of preeclampsia. Moreover, most authors, with only a few exceptions, failed to identify the arm used to record blood pressure. This is of great importance, since turning the patient from the left side on to her back with blood pressure recorded from the right (superior) arm will result in a predictable increase in diastolic pressure of approximately 10 to 12 mm Hg because of the increase in hydrostatic pressure relative to the level of the heart.[53] Furthermore, it is uncertain in most reports whether tests were assessed in a double-blind fashion. Several of the publications state that the results of the tests were not revealed to the physicians in charge or to the patients themselves, but it is not mentioned specifically whether the diagnosis of preeclampsia was made without knowledge of the test results. In summary, the results of the roll-over test are highly variable among different investigators, and there is poor reproducibility in the same patient. Studies in the literature report sensitivities varying between 0% and 93%, specificities between 54% and 91%, and false-positive results up to 90%. The final conclusion must be that, although the roll-over test has gained some popularity

because of its simplicity, it is of little use clinically as a predictive test. However, it may be useful to screen patients for study purposes.

Infusion of epinephrine and norepinephrine. The pressor effects of epinephrine infused in physiologic[54] and pharmacologic[55-57] doses appear to be more pronounced in women with mild preeclampsia than in normotensive pregnant women. Raab et al.[54] investigated the pressor effects of two doses of epinephrine in 163 normotensive pregnant women between 28 and 34 weeks' gestation. They noted an increase in systolic blood pressure that was higher in women who became hypertensive later in pregnancy than in women who remained normotensive. However, there was extreme variability in blood pressure responses and considerable overlap between responses of normal and abnormal groups. Also, the pressor response to norepinephrine appears to be enhanced in hypertensive pregnant patients as compared with normotensive pregnant women.[55-57]

Infusion of angiotensin II. In 1961, Abdul Karim and Assali[58] reported that intravenous infusion of angiotensin II (angiotonin) caused a smaller rise in blood pressure in pregnant women than in nonpregnant women. The relative refractoriness to the pressor effects of angiotensin II in normal pregnancy was later confirmed in several studies.[59-61] In addition, it was found that this refractoriness is lost to a marked extent in women with preeclampsia.[61, 62] Gant et al.[33] used the determination of the sensitivity to the pressor effects of infused angiotensin II to predict the development of preeclampsia. The study included 192 randomly selected young (13 to 17 years old) primigravid and 10 nonpregnant gynecologic patients. The authors first determined the amount of angiotensin II infused per kilogram of body weight per minute needed to raise the diastolic blood pressure by 20 mm Hg. The average so-called effective pressor dose was found to be about 8 ng/kg/min in nonpregnant individuals and in early (7 to 10 weeks) pregnancy. The required dose needed was approximately twofold (15 ng/kg/min) by 28 weeks and fell gradually thereafter to a level of 11 to 12 ng/kg/min at term. Up to about 20 weeks' gestation, all pregnant women showed this refractoriness to the pressor effects of angiotensin II that was thought to be a physiologic feature of pregnancy. However, in women in whom preeclampsia ultimately developed, the refractoriness gradually decreased and between 28 and 32 weeks the effective pressor dose had returned to nonpregnant values. Of the total group of 192 pregnant women, 153 underwent at least one angiotensin II infusion test between the twenty-eighth and thirty-second week. Of these, 103 remained normotensive and 50 subsequently developed preeclampsia in the third trimester. Of the 103 women who remained normotensive, 13 had an effective pressor dose of <8 ng/kg/min (positive test); of the 50 women who became hypertensive, 45 (90%) had at least one positive test.

The angiotensin sensitivity test is a rather complicated and time-consuming procedure, which may be the reason that its validity in predicting preeclampsia has been subsequently assessed in very few clinical investigations. There is one other study from the United States,[63] one from Mexico,[64] two from Europe,[51, 52] and one from Japan.[65] The results of these studies are summarized in Table IV. The numbers are small, and the definitions of a positive test and of preeclampsia are different. Thus it is very difficult to compare these studies.

In conclusion, the angiotensin sensitivity test is too complicated and time consuming to be used as a clinical screening procedure. It may, however, be useful at 28 weeks' gestation for research purposes to distinguish between patients with a high risk of approximately 50% and those with a low risk of 1% to 5% of preeclampsia, assuming an incidence of 10% to 15%.[51, 66]

Biochemical and hematologic markers. Concentrations of a large number of constituents of blood and urine, including hormones, have been shown to change in preeclampsia. Some of these changes have been proposed to be of value in the prediction of early diagnosis of the disorder and some of them will be discussed in the following paragraphs.

Broughton Pipkin et al. (Broughton Pipkin F, Baker PN, Symonds EM. Platelet angiotensin II receptors in predicting preeclampsia. Personal communication) recently studied platelet angiotensin II receptors in normotensive and hypertensive pregnancies. Platelets share various characteristics with vascular smooth muscle cells and are increasingly being used as readily accessible models for smooth muscle cells. This study showed that a physiologic fall in platelet angiotensin II binding occurs in early pregnancy, which is parallel to that of the vascular response to angiotensin II. It was found that platelet angiotensin II receptors are increased in preeclampsia, probably as an expression of the altered angiotensin II levels; this increase was shown to precede the increase in blood pressure. The Nottingham group reported a positive predictive value of 77.8%, a negative predictive value of 82.9%, a sensitivity of 87.5%, and a specificity of 86.7% for nulliparous women ($n = 23$) in predicting preeclampsia between 26 and 32 weeks' gestation. Also, recently an increase in the sensitivity of platelet calcium to arginine vasopressin was proposed to be useful as an early predictor of subsequent preeclampsia.[67] It was shown that the sensitivity of platelet intracellular calcium levels to arginine vasopressin in patients with subsequent preeclampsia is already increased at end of the first trimester, as compared with normotensive pregnancies.

Both these studies on platelet pathophysiologic characteristics underline the concept of preeclampsia as a trophoblast-dependent process that is mediated by a disturbed platelet-endothelium interaction. Although the potential value of platelet angiotensin II receptors and the increase in the sensitivity of platelet calcium to arginine vasopressin have been assessed only in small numbers of patients, these two methods hold great promise for studying cardiovascular pathophysiologic parameters in normotensive and hypertensive pregnancies and for the development of a predictive test.

Plasma volume, hemoglobin concentration, and hematocrit. It has been reported by many authors that the average plasma volume is less in patients with preeclampsia.[68] There is evidence that plasma volume contraction may precede the blood pressure rise in preeclampsia at least in some of the cases[69-71]; however, the numbers of patients studied are small, and there is considerable overlap between values of plasma volume in normal and abnormal groups. In addition, dye-dilution techniques for estimating plasma volume are subject to serious criticism,[72] and they are too complicated to be used as a screening procedure in standard antenatal care. The contraction of plasma volume that is often observed in preeclampsia may be revealed by an elevation of or a rise in hemoglobin concentration or hematocrit.[73] In addition, many obstetricians use serial measurements of the hematocrit to monitor the clinical course of preeclampsia. In a large retrospective study comprising >54,000 singleton pregnancies, Murphy et al.[74] showed a highly significant correlation in nulliparous and parous women between the frequency of occurrence of preeclampsia and the hemoglobin concentration at first visit before 24 weeks. In primigravid women, the frequency of subsequent preeclampsia ranged from 7% at hemoglobin values <10.5 gm/dl to 42% at hemoglobin concentrations >14.5 gm/dl.

Uric acid. In 1925, Stander et al.[75] reported increased serum uric acid levels in women with preeclampsia. Many later investigators confirmed this finding and demonstrated a positive correlation between the magnitude of serum uric acid levels, clinical severity of preeclampsia, and perinatal outcome.[76-79] On the basis of the results of a prospective (but not blinded study) in 332 hypertensive pregnant patients with mixed parity, Redman et al.[78] concluded that plasma uric acid levels constitute a better indicator than blood pressure as a prognosis for fetal outcome. However, other studies did not confirm these findings.[80]

The results of many studies[81-83] but not of others[84] in normotensive pregnant women suggest that serum uric acid levels may begin to rise before the appearance of hypertension and proteinuria. However, patients studied included nulliparous and parous women, some of them with renal disease or treated chronic hypertension, and the presentation of the data does not allow a reliable evaluation of the results. Moreover, the predictive value of uric acid determination was not assessed in a double-blind fashion in any of these studies.

In conclusion, as for other signs of preeclampsia, hyperuricemia is nonspecific. As yet there is no evidence that determination of uric acid levels can be used as a screening test to predict the later development of the disease. In patients with established preeclampsia, serum uric acid levels may reflect severity of the disease process. For that reason, uric acid levels can be used in the clinical management of these patients to monitor the course of the disease.

Urinary calcium excretion. Taufield et al.[85] reported that established preeclampsia is associated with hypocalciuria. The authors investigated a group of 40 pregnant women, 20 nulliparous and 20 multiparous, in the third trimester of pregnancy; 10 were normotensive, five had transient hypertension, six had chronic hypertension, six had chronic hypertension with superimposed preeclampsia, and 12 had preeclampsia. Urinary calcium excretion was not different between normotensive women and patients with transient or chronic hypertension, but it was significantly lower (13% to 25% of normal pregnant values) in preeclamptic patients. In these patients the fractional excretion of calcium was also reduced, suggesting increased tubular reabsorption.

In a recent investigation in 88 pregnant women with mixed parity (11.4% incidence of preeclampsia), Rodriguez et al.[21] assessed the value of the urinary calcium/creatinine ratio between 24 and 34 weeks' gestation. A calcium creatinine ratio of ≤ 0.04 was reported to have a sensitivity of 70%, a specificity of 95%, a positive predictive value of 64%, and a negative predictive value of 96%. In contrast, Roelofsen et al.[86] reported no difference in urinary excretion rates of calcium between normotensive and hypertensive pregnant women. The findings of these authors may be caused by the fact that they studied a very heterogeneous population. It is important to note that the results of Taufield et al.[85] were recently confirmed by Huikeshoeven and Zuijderhoudt.[87] Further prospective studies are needed to support or refute these findings and to determine whether a decrease in urinary calcium excretion could be used as a predictor of the disease.

Urinary excretion of prostacyclin metabolites. Evidence is accumulating that a relative deficiency of vascular prostacyclin plays an important role in the development of preeclampsia.[5] Fitzgerald et al.[88] reported that a reduction in the urinary excretion of 2,3-dinor-6-keto-prostaglandin F_1, a major metabolite of prostacyclin, precedes the development of clinical disease. Urine was collected at 11 to 20 weeks' gestation, 20 to 29 weeks' gestation, and between 28 weeks' gestation and term in 67 pregnant women considered to be at risk for preeclampsia. Patients were retrospectively allocated to one of four predefined groups (preeclampsia, chronic hypertension, hypertension in labor, or normotensive) by observers who were blinded as to the results of the biochemical analysis. Excretion of 2,3-dinor-6-keto-prostaglandin F_1 was increased throughout pregnancy in all pregnant women, as compared with that in normotensive nonpregnant subjects. However, 2,3-dinor-6-keto-prostaglandin F_1 excretion was significantly reduced in 12 women (18%) in whom preeclampsia developed later in pregnancy, as compared with that in pregnant women who remained normotensive or who became hypertensive during labor. In this study they found no difference between normotensive subjects and patients with pregnancy-induced hypertension in their pressor response to angiotensin II, despite a difference in prostacyclin biosynthesis. The authors stated that excretion of <400 pg 2,3-dinor-6-keto-prostaglandin F_1 per milligram creatinine at 20 to 28 weeks' gestation was associated with a 65% risk of preeclampsia, but they did not provide data to calculate sensitivity and specificity. A study of a larger population is needed to assess the predictive power of determination of urinary 2,3-dinor-6-keto-prostaglandin F_1 excretion.

Enzymes and hormones. Concentrations of various enzymes in serum or plasma have been studied in patients with preeclampsia, mainly to assess placental function.[3] After a brief period of clinical enthusiasm, none of these enzymes has been shown to be of use as an early indicator of hypertensive disease in pregnancy or as a biochemical measure of its severity.

As an extension of earlier studies,[82, 89] other investigators[90, 91] have adduced evidence that serum levels of deoxycytidylate deaminase are increased if preeclampsia develops but not in chronic hypertension. These investigators performed at least two determinations of deoxycytidylate deaminase, one at first visit and one in the third trimester, in sera of 2460 pregnant women, the parity of whom was not reported. An abnormally high value was defined as a value ≥ 2 SD above the mean of control values obtained in apparently normal pregnancies. A total of 133 women (5.4%) had pregnancy-induced hypertension or preeclampsia. All of 73 patients with moderate to severe preeclampsia and 52 of 60 women with mild disease had abnormally high levels. High levels were also observed in nine patients with a hepatic disorder. Only 53 other patients had high deoxycytidylate deaminase levels (false positive). It should be emphasized that the majority of the patients already had clinical signs of preeclampsia at the time of determination of deoxycytidylate deaminase values. No abnormally elevated levels were found before 24 weeks' amenorrhea and very few ($n = 4$) before 28 weeks, which makes it unlikely that this test can be used to predict the subsequent development of preeclampsia.

Wood and Durham[92] measured plasma cystyl aminopeptidase (oxytocinase) from 28 weeks' gestation until delivery in 92 primigravid women and reported significantly higher levels of the enzyme at 30 and 32 weeks in women in whom preeclampsia developed later. Further studies of plasma cystyl aminopeptidase in a larger number of patients are required to evaluate the possible predictive value of this plasma enzyme.

It has been claimed that the levels of the placental protein hormone termed *pregnancy-associated plasma protein A* are raised toward the end of the second trimester in women who are likely to have preeclampsia.[92-94] In a more recent study, it was found that measurement of the placental proteins pregnancy-associated plasma protein A, human placental lactogen, and SP1 (Schwangerschaft protein) is of no use in predicting the later development of preeclampsia.[95] Some studies suggested that β-human chorionic gonadotropin determination may have value for early detection of preeclampsia. However, because levels in both normal and preeclamptic pregnancies show a larger scatter and overlap, the practical usefulness of β-human chorionic gonadotropin determination as a predictive test seems limited.[96, 97]

The rate at which the placenta clears maternal blood of isotope-labeled dehydroisoandrosterone sulfate for estradiol synthesis has been postulated to reflect uteroplacental perfusion.[98] A longitudinal study of the metabolic clearance rate of this substance in women who developed preeclampsia later in pregnancy showed that during the first half to two thirds of pregnancy placental perfusion was similar to or even above that in women who remained normotensive. The metabolic clearance rate began to fall 2 to 4 weeks before hypertension was detected, by which time it was only 35% to 50% of normal.[99] These results have not been confirmed in other studies. In addition, the late occurrence of a fall in metabolic clearance rate of dehydroisoandrosterone sulfate and the important interindividual variation make it unlikely that this test may be used for prediction purposes.

Coagulation factors and platelets. Evidence for the occurrence of abnormal coagulation processes and platelet activation was originally based on the finding, as early as 1893, of fibrin deposits and thrombi in vessels of various organs of women who died of eclampsia. In later years, all factors of the extrinsic and intrinsic coagulation system have been extensively studied in women with preeclampsia, either directly or indirectly by means of various clotting tests. A complicated coagulation index has been proposed to predict the clinical progress of preeclampsia.[100] These studies have recently been reviewed and analyzed in detail.[101] The results are generally equivocal and do not suggest marked consumption of coagulation factors in most patients with preeclampsia. The most frequently occurring hemostatic abnormalities in patients with preeclampsia are a rise in the factor VIII–related antigen level and a reduced antithrombin III concentration.

Thrombin-induced coagulation, vascular endothelial damage, and platelet aggregation increase the circulating levels of factor VIII–related antigen (von Willebrand factor) and the ratio of that antigen to coagulant factor VIII. Some authors have reported an early rise of these factors in preeclampsia[102] whereas others have demonstrated a positive correlation between plasma factor VIII–related antigen activity or the level of the ratio of factor VIII–related antigen and coagulant factor VIII and the clinical severity of the disorder, growth retardation, and perinatal mortality.[103-108] However, there appears to be a particularly good correlation between plasma factor VIII–related antigen activity and the occurrence of fetal growth retardation. It can be concluded from these studies that finding this antigen or the factor VIII–related antigen-to-coagulant factor C ratio elevated constitutes a useful and quite early indicator of both the severity and the degree of placental insufficiency.

Decreased levels of antithrombin III have been demonstrated in a majority of patients with preeclampsia but not in pregnant women with chronic hypertension.[109, 110] However, early antithrombin III determinations had no value in predicting the development of preeclampsia later in pregnancy.[111] In addition, Dekker[5] found no difference in antithrombin III activity between angiotensin II–sensitive and angiotensin II–insensitive pregnant women at 28 weeks' gestation.

de Boer et al.[112] observed thrombin/antithrombin III levels more than twice as high in preeclampsia as those in gestational age–matched control subjects. Also, protein C levels were reduced substantially compared with normal pregnancy. However, there are no data on thrombin/antithrombin III and protein C levels before the onset of preeclampsia. Thus further prospective longitudinal studies are needed to evaluate their possible predictive value.

Recently attention has been focused on plasma levels of fibronectin, a glycoprotein involved in coagulation, platelet function, tissue repair, and the vascular endothelial basement membrane. Fibronectin levels were found to be markedly elevated in preeclamptic patients[113-116] and correlated with low antithrombin III levels and with the degree of proteinuria.

Ballegeer et al.[111] measured fibronectin and plasminogen activator inhibitor-1 levels in 120 normotensive primigravid women during the first, second, and third trimesters of pregnancy. Thirty-two women (26.6%) had preeclampsia. Increased levels of fibronectin at 25 to 36 weeks of pregnancy (greater than or equal to mean + 2 SD of the healthy women, or >140%) were found in 31 of the 32 women with hypertension (sensitivity 96%, specificity 94%). Fibronectin levels increased 3.6 ± 1.9 weeks earlier than the onset of hypertension or proteinuria. Increased levels of plasminogen activator inhibitor-1 at 25 to 32 weeks (≥280 ng/ml) were found in 16 of the 32 women (sensitivity 50%, specificity 95%). The authors concluded that increased fibronectin levels are the best predictor of preeclampsia and that its level in plasma increases several weeks before the development of hypertension.

Lockwood and Peters[117] reported that increased plasma levels of ED1+ (extra type III domain) cellular fibronectin, almost exclusively localized to endothelium, may precede the clinical signs of preeclampsia. They found that ED1+ fibronectin levels were significantly higher in the preeclampsia group in the first and second trimesters, before clinical evidence of the disorder. The data are very promising but do not allow an assessment of the predictive value of this new biochemical marker.

Many reports in the literature indicate that in patients with preeclampsia the platelet count is lower than in uncomplicated pregnancies[118-120] and that thrombocytopenia may occur as an early[120] but also as a relatively late feature of the disorder. In addition, thrombocytopenia is not a feature in pregnant patients with chronic hypertension without superimposed preeclampsia.[121] However, platelet behavior in women with preeclampsia is extremely variable, and reduced platelet counts are not found in all cases, not even in eclampsia.[80] Results of various large studies suggest that approximately 20% of patients with preeclampsia have thrombocytopenia, varying between 7% in mild preeclampsia and 50% in severe preeclampsia-eclampsia.[119] Thrombocytopenia is usually mild; in some cases it may be accompanied by hemolysis and elevated liver enzymes, a typical constellation of abnormalities that has been named the HELLP syndrome.[121] Episodes of platelet activation and consumption are also reflected in increased plasma levels of β-thromboglobulin[122-124] and platelet factor IV[125] in some patients with preeclampsia but not with chronic hypertension. However, the results of these studies indicate that platelet behavior in preeclampsia is extremely variable, between patients and within one patient.

In conclusion, determination of factor VIII–related antigen activity or its ratio to coagulant factor VIII, plasma antithrombin III concentrations, and platelet counts may be of value in the management of preeclampsia. However, there is no convincing evidence that these determinations are of any value for prediction or early diagnosis of the disease. Presently, the measurement of total fibronectin or ED1 + fibronectin holds the greatest promise as a predictive test for the development of preeclampsia.

Doppler ultrasonography methods. The development of continuous wave and pulsed range-gaged Doppler ultrasonographic systems has made it possible to study the perfusion of deep-lying vessels such as the arcuate arteries and other branches of the uterine vasculature.[126-129] Because of the as yet inevitable errors in the measurement of volume flow, most emphasis has been put on the quantitative examination of flow velocity waveforms. The velocity waveforms in the branches of the uterine arteries in normal pregnancy show an increase in end-diastolic flow velocity between 14 and 20 weeks; there appears to be no further change in this pattern of low pulsatility and high diastolic velocity until term.[128-130]

In their first study, Campbell et al.[127] observed arcuate artery waveform patterns with reduced end-diastolic velocities suggestive of an elevated uteroplacental vascular resistance in 14 of 31 patients with complicated pregnancies. Of these 14 patients, 10 had preeclampsia and eight were eventually delivered of a small-for-gestational-age infant. Of the 17 patients with normal arcuate artery flow velocity waveforms, only four had preeclampsia, and six of the fetuses were growth retarded. The results of this study were later supported by those of a larger, nonblinded study by Trudinger et al.[129] On the contrary, Hanretty and Whittle[131] found no overall difference in uteroplacental waveforms between women with normal pregnancies and those with established preeclampsia.

The first prospective study in which the predictive value was determined of the occurrence of abnormal arcuate artery waveforms in the second trimester has been reported by Campbell et al.[127] A group of 149 unselected pregnant women was investigated; 17 were delivered elsewhere and there were incomplete records for six cases; of the remaining 126 women, 41 were nulliparous. Arcuate artery waveforms were determined between 16 and 18 weeks' gestation, and the clinicians who took care of the patients were not informed about the results. Of the 76 women with normal waveforms, preeclampsia developed in five and five other pregnancies were complicated by isolated fetal growth retardation. Of the 50 women with abnormal waveforms, preeclampsia developed in 10 and 10 pregnancies were complicated by fetal growth retardation alone. The sensitivity of determination of arcuate artery waveforms at 16 to 18 weeks' gestation as a test to predict preeclampsia or fetal growth retardation was 68%; specificity was 69%. The predictive value of a positive test was 42% and of a negative test 87%. The authors did not present an explanation of the remarkable finding of 40% abnormal waveforms in an unselected sample of pregnant patients or of the high incidence (24%) of complicated pregnancies. Similar results were reported by Arduini et al.[132]; they studied 60 high-risk pregnancies at 18 to 20 weeks' gestation (incidence of preeclampsia, 36.6%). The validity of uteroplacental waveforms analysis was as follows: sensitivity, 63.6%; specificity, 84.2%, positive predictive value, 70%, negative predictive value, 80%.

In a study from the Fetal Welfare Laboratory at St. George's Hospital, London, the results of Doppler ultrasonography as a screening test for any degree of hypertension were somewhat disappointing, with a sensitivity of only 25% at 24 weeks but with a sensitivity of nearly 100% for severe preeclampsia or fetal growth retardation.[133, 134]

A predictive value of about 50% reported in the studies of Campbell et al.[128] and Steel et al.[134] are not approached by several recent studies. Although Newnham et al.[135] reported a significant association between uteroplacental systolic/diastolic ratios at 24 weeks' gestation and subsequent fetal hypoxia (sensitivity, 24%; specificity 93.9%), they could not find a relationship between elevated systolic/diastolic ratios and preeclampsia. In addition, Jacobson et al.[136] studied the value of Doppler assessment of the uteroplacental circulation in predicting preeclampsia or fetal growth retardation in 136 high-risk women. In this study a low fetal abdominal circumference at 20 to 24 weeks or an increasing maternal plasma uric acid concentration at 24 weeks was as predictive as an elevated resistance index. The authors concluded that although elevated resistance indices occur more commonly in women with fetal growth retardation or preeclampsia, the correlation is not close enough to be clinically useful as a screening test.

Measurement of arcuate artery blood flow velocities between 16 and 24 weeks' gestation may diagnose impaired trophoblast invasion of the spiral arteries and may therefore have great potential in predicting pregnancies destined to become complicated by preeclampsia or fetal growth retardation. In addition, this method may be useful to monitor the course of the hypertensive disorder and the effects of treatment. Probably Doppler ultrasonography of the uteroplacental circulation is useful only as a predictive test for the later development of severe preeclampsia or fetal growth retardation,[132-134] but this may be clinically important because most hypertension in pregnancy probably represents an enhanced physiologic adaptation to pregnancy.

Even more simple ultrasonographic techniques may be of use in identifying women with a high risk of hypertension in pregnancy. Koffinas et al.[137] showed that patients with unilateral placentas have a 2.8-fold greater incidence of preeclampsia than women with central placentas. These results are supported by Schulman et al.[138] In this study it was reported that women with preeclampsia have a dominant unilateral uteroplacental blood flow.

Comment

More than 100 clinical, biophysical, and biochemical tests have been recommended for predicting the development of preeclampsia. The findings of numerous studies have been inconsistent and contradictory, owing to the heterogeneity of the populations studied and variations in the definitions used for hypertensive disorders during pregnancy and in the methods used to express results. Future studies should adhere to strict criteria to diagnose and classify hypertension during pregnancy. In addition, only healthy, nulliparous pregnant women should be included.

From this review it is obvious that currently there is no ideal predictive test that fulfills all desired criteria. The value of the roll-over test remains controversial at the least. The angiotensin sensitivity test is useless in clinical practice, but it may be considered useful for research purposes because it can be done in early pregnancy and has a high predictive value. An increased second-trimester MAP only predicts transient hypertension instead of the real disease, preeclampsia-eclampsia.

The ultimate goal in the management of preeclampsia is to be able to detect the disease in the the early stages and have available a therapy that either cures it or at least ameliorates its progression in an attempt to achieve fetal maturity. Concerning the development of an easy, reliable predictive test for the development of severe preeclampsia, the focus of attention is on total or ED 1+ fibronectin and Doppler-flow studies of the uteroplacental circulation. Doppler-flow studies of the uteroplacental circulation express a low to average predictive value; however, they are easy to carry out, inexpensive, and noninvasive. In addition, Doppler-flow studies can be done in early pregnancy and show a high sensitivity for severe preeclampsia with associated perinatal or maternal morbidity or mortality. Therefore Doppler-flow studies of the uteroplacental circulation are very suitable for therapeutic intervention to reduce the incidence of preeclampsia and its complications. The recent study on ED 1+ fibronectin demonstrating an increase in ED 1+ fibronectin in preeclampsia already occurring in the first and second trimesters before any clinical evidence of disorder is extremely promising. Also, the recent use of platelet angiotensin II receptors as an alternative, inexpensive and practical angiotensin sensitivity test and the increased platelet calcium response to arginine vasopressin may offer great promise in the future.

Effects of maternally administered epidermal growth factor on placental permeability

Francis Mimouni, MD, Steven B. Hoath, MD, and Gail Hammond, BS
Cincinnati, Ohio

Epidermal growth factor is a well-studied modulator of epithelial membrane structure and function. Mammalian placentas are a rich source of epidermal growth factor receptors, but the role of epidermal growth factor in placental pathophysiologic conditions is unclear. To determine whether epidermal growth factor could affect mechanisms of placental transfer, we used an in situ rat placental perfusion model. Fourteen Sprague-Dawley rats that were 20 days pregnant were randomized to epidermal growth factor or placebo during placental transport experiments. We chose ethylenediaminetetraacetate tagged with chromium 51 as a marker of placental permeability. Epidermal growth factor treatment led to a dramatic increase of maternofetal clearances of chromium 51–ethylenediaminetetraacetate. We conclude that maternally administered epidermal growth factor has a potent action on placental permeability. (AM J OBSTET GYNECOL 1991;165:173-6.)

Key words: Epidermal growth factor, placenta, placental transport

Because of the importance of the placenta in maintaining mammalian pregnancy, there is increasing interest in biochemical factors that regulate placental function and allow the placenta to act as a critical interface between mother and fetus. Recently it has been recognized that the placenta is a rich source of growth factors and growth factor receptors,[1] as well as protooncogenes.[2] These findings have led to the suggestion that these molecular regulators play an important role in the control of placental or fetal growth. One of the best-studied growth factors in this regard is epidermal growth factor. Although the human placenta is one of the richest known sources of epidermal growth factor receptor,[3] the roles of epidermal growth factor and that of the structurally homologous protein transforming growth factor-α remain unclear.

In the placenta of normal, near-term fetal rats,[4, 5] there is a developmental increase in epidermal growth factor–binding sites; this is also the case for the human placenta during the last half of gestation.[6, 7] Placental membranes of intrauterine growth–restricted rats have increased binding of epidermal growth factor,[5] whereas placentas from streptozocin-treated diabetic rats have decreased the binding of epidermal growth factor.[4]

Since epidermal growth factor has been demonstrated to influence ionic signal transduction (sodium-hydrogen exchange)[8] and to increase transport of α-aminoisobutyrate[9] and deoxyglucose[10] in isolated cell culture systems, we undertook a study of the effect of maternally administered epidermal growth factor on placental transport. As an index of placental permeability, we selected chromium 51–ethylenediaminetetraacetate (EDTA), a known diffusion marker, believed to travel across the placenta by means of "small pores,"[11] because of its small molecular size. We used an in situ system of placental perfusion in the rat[12] to test the null hypothesis that maternally administered epidermal growth factor would not affect placental transport of ^{51}Cr-EDTA.

Material and methods

All chemicals were reagent grade, purchased from Sigma Chemical Co. (St. Louis). Radioisotopes were purchased from New England Nuclear (Boston). Receptor-grade epidermal growth factor was purchased from Bioproducts for Science (Indianapolis). Epidermal growth factor is extracted from mouse salivary glands and is ≥99% pure.

Animals and surgical procedure. Fourteen time-mated Sprague-Dawley rats were purchased from Zivic Miller Lab Inc. (Allison Park, Pa.) on day 14 of gestation. They were housed in individual cages and allowed free access to water and Purina Rat Chow (Ralston-Purina Co., St. Louis).

From the Division of Neonatology, Department of Pediatrics, University of Cincinnati College of Medicine.

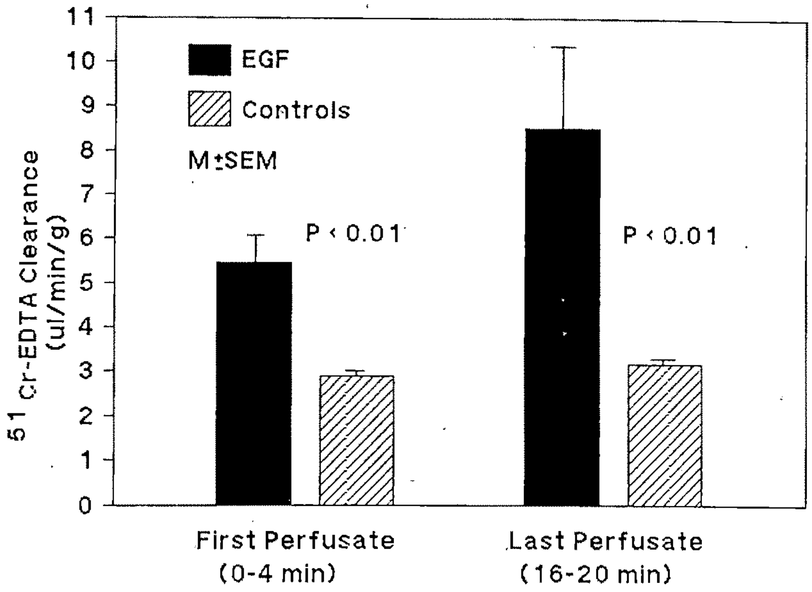

Fig. 1. Maternofetal clearances of ^{51}Cr-EDTA in epidermal growth factor versus placebo-infused animals.

Table I. Comparability of epidermal growth factor and control groups

Variable	*Epidermal growth factor*	*Control*	*Difference*
Maternal weight (gm)	418 ± 41	443 ± 33	NS
Fetal weight (gm)	4.0 ± 0.5	3.9 ± 0.2	NS
Placental weight (gm)	0.51 ± 0.04	0.49 ± 0.08	NS

NS, Not significant.

Placental perfusion. On day 20 of gestation, the dams were anesthetized with 110 mg/kg sodium thiobutabarbital, which was injected intraperitoneally. The maternal rectal temperature was maintained at 37° C through the experiment. A maternal jugular vein was cannulated for injection of tracers; a carotid artery, for blood pressure monitoring and blood sampling; and a femoral vein, for the administration of epidermal growth factor (or placebo). Maternal arterial pressure and perfusion pressure were measured with precalibrated Gould-Statham pressure transducers (Gould Inc., Cleveland) and recorded continuously on a chart recorder.

After laparotomy and hysterotomy, one of the fetuses was delivered. Modified Krebs-Ringer solution containing 118 mmol/L sodium chloride, 4.7 mmol/L potassium chloride, 1.25 mmol/L calcium chloride, 1.18 mmol/L potassium orthophosphate dihydrate, 1.18 mmol/L magnesium sulfate, 25 mmol/L sodium bicarbonate, 11 mmol/L glucose, and 3.5% dextran (40,000 d) was gassed continuously with a mixture of 95% oxygen and 5% carbon dioxide at 37° C and pumped by a peristaltic pump (Hake-Buchler, Saddle Brook, N.J.) into the fetal circulation of the placenta, through a cannula in the umbilical artery. The perfusion rate varied from 0.28 to 0.39 ml/min between experiments but remained constant during any individual experiment. After a single pass through the placenta, perfusate effluent was collected from a cannula in the umbilical vein.

Each fetus whose placenta was perfused was removed after the vessels had been cannulated, blotted with tissue paper, and weighed to an accuracy of 0.1 mg with a Mettler H51 AR balance (Mettler Corp, Cleveland). At the end of the experiment the perfused placenta was detached from the uterine wall, and its wet weight was measured to an accuracy of 0.001 mg after fetal membranes and the umbilical cord had been dissected and discarded.

Randomization. Animals were randomized to maternal administration of epidermal growth factor ($n = 8$) or placebo ($n = 6$). Epidermal growth factor or placebo was given through the catheter, which was inserted through the maternal femoral vein. Epidermal growth factor was given as a bolus of 5 μg, followed by continuous infusion of 0.8 μg/min. This infusion was continued until the end of the experiment. The investigators were blinded as to whether the animal received epidermal growth factor in normal saline solution or placebo (saline solution alone).

Placental transfer. After 20 minutes of epidermal growth factor or placebo infusion, 40 μCi of ^{51}Cr-EDTA (500 to 800 mCi/mg) in 0.1 to 0.2 ml 0.9% sodium chloride was injected at time 0 as a bolus into the maternal circulation through a cannula in the jugular vein. At approximately 3, 13, and 25 minutes, 0.5 ml heparinized maternal blood samples were drawn from a cannula in the carotid artery for radioisotope counting. Three 4-minute collections of perfusate effluent were taken in each experiment. ^{51}Cr activity (in counts per minute) in aliquots of plasma and of perfusate effluent were counted for 10 minutes in a Packard 5330 auto-γ spectrometer (Packard Instruments Co.).

Exclusion criteria. A successful perfusion was one in which the perfused placenta was uniformly blanched (because of removal of fetal blood), and placental perfusate effluent recovery was 95% to 100% of the inflow volume. Exclusions were made before counting of plasma and perfusate samples.

Calculations. The steady-state clearance of ^{51}Cr-EDTA from maternal plasma to each perfusate sample (in microliters per minute) was defined as maternofetal clearance of ^{51}Cr-EDTA (K_{mf} ^{51}Cr-EDTA):

$$K_{mf}\ {}^{51}\text{Cr-EDTA} = (P \times F/M) \times 1000$$

where P is the ^{51}Cr concentration (counts per minute per milliliter) in perfusate effluent samples, M is the ^{51}Cr concentration (counts per minute per milliliter) in the maternal plasma at the midpoint of each 4-minute collection period, and F is the rate at which the perfusate was pumped through the placenta (milliliters per minute). To normalize for differences in placental size in different experiments, the clearance was related to the wet weight of the perfused placenta (microliters per minute per gram of placenta).

Statistics. The data are presented as mean ± SE. Differences between means in each group and over time were analyzed by means of repeated measures analysis of variance; $p < 0.05$ was considered significant.

Results

Epidermal growth factor and control groups were comparable by maternal, fetal, and placental weight at baseline (Table I).

Clearances of ^{51}Cr-EDTA were significantly affected by the infusion of epidermal growth factor; the K_{mf} ^{51}Cr-EDTA at baseline (i.e., after 20 minutes of epidermal growth factor or placebo infusion), which was calculated from the first effusate collection, was almost doubled in the epidermal growth factor group (5.45 ± 0.61 vs 2.88 ± 0.15 µl/min/gm, $p < 0.01$); it increased further in the epidermal growth factor group, to reach a value of 8.52 ± 1.84 µl/min/gm ($p < 0.001$) in the last perfusate, whereas it remained the same in the control group at 3.16 ± 0.14 µl/min/gm (not significant, compared with baseline) (Fig. 1).

Comment

Experimentally our results demonstrate that maternal-fetal ^{51}Cr-EDTA clearance is increased by maternal administration of epidermal growth factor. In adult rats epidermal growth factor is promptly removed from the circulation by hepatic sequestration and biliary secretion.[13] Thus, because of the fact that we could not infuse epidermal growth factor directly to the uterine artery for technical reasons, we used a dose of epidermal growth factor that was clearly pharmacologic both for bolus and for continuous infusion. Whether maternal serum concentrations remained elevated within the physiologic or the pharmacologic range after hepatic degradation was not determined in this pilot study. Regardless of this consideration, the mechanism by which placental permeability was increased by the exogenous growth factor requires explanation. Theoretically, augmented permeability to small molecules could be due either to an increase in "pore" number or to "pore" size.[11]

Epidermal growth factor has been demonstrated to have potent vasoconstrictor or vasodilator effects in different species, depending on the vascular bed studied.[14-16] An increase in uterine blood flow induced by epidermal growth factor, however, would have been unlikely to enhance ^{51}Cr-EDTA clearance; indeed ^{51}Cr-EDTA is a known diffusion marker that crosses the placenta according to a concentration gradient and therefore is unlikely to be affected by an increase in flow.[11]

We speculate that epidermal growth factor might be one of the regulators of placental transport of nutrients that cross the placenta by simple diffusion. This speculation would be consistent with the observation that intrauterine growth retardation in the rat increases epidermal growth factor binding to the placenta[5] (which theoretically could increase non-energy-dependent transfer of nutrients through the placenta). In contrast, in situations of excessive fetal nutrient availability such as the diabetic pregnancy in the rat, epidermal growth factor binding to placenta is reduced[4] (which theoretically could decrease non-energy-dependent transfer of nutrients through the placenta). Whether epidermal growth factor does or does not have a physiologic effect on placental function, its potent action on placental permeability, as demonstrated in this study, might provide a unique model for studying the molecular regulation of nutrient transport across the placenta.

All known biologic effects of epidermal growth factor are mediated through epidermal growth factor binding to specific cell-surface receptors.[17] Placebo (normal saline solution) did not have any measurable effect on placental permeability. We cannot, however, exclude the possibility that transforming growth factor-α, the only other protein known to bind to the epidermal growth factor receptor,[18, 19] may elicit similar changes in placental permeability.

Effect of clomiphene citrate treatment on endometrial estrogen and progesterone receptor induction in women

Marc A. Fritz, MD,[a] **Ronald T. Holmes,**[b] **and Edward J. Keenan, PhD**[b, c]

Wright-Patterson Air Force Base, Ohio, and Portland, Oregon

A direct adverse effect of clomiphene citrate on the endometrium has been presumed, and interference with estrogen receptor–mediated endometrial estrogen receptor and progesterone receptor induction has been implicated as the mechanism responsible for an increased incidence of luteal phase deficiency in association with clomiphene citrate treatment. To clarify the net influence of clomiphene administration on endometrial steroid receptor induction, we studied five normal ovulatory women, in both a spontaneous and clomiphene-induced (150 mg/day, cycle days 5 to 9) ovulatory cycle. From cycle day 11 blood samples were obtained daily and urinary luteinizing hormone determinations were performed twice daily. Endometrial biopsy was performed on the day of the urinary luteinizing hormone surge and again 13 days after the surge. Serum levels of follicle-stimulating hormone and luteinizing hormone were determined by immunoradiometric assay, estradiol and progesterone by radioimmunoassay, and clomiphene citrate isomer concentrations in treatment cycles by reversed-phase high-performance liquid chromatography and fluorescence detection. Total, cytosolic, and salt-extracted nuclear endometrial estrogen receptor and progesterone receptor concentrations were determined by enzyme-linked immunoassay. Serum estradiol was threefold to fivefold higher ($p < 0.05$) in clomiphene-induced than in spontaneous cycles 8 and 10 days before the luteinizing hormone surge, and progesterone was increased ($p < 0.05$) from the day of the surge to end of the cycle. Serum enclomiphene rose to plateau between 12 and 6 days before the luteinizing hormone surge (4.1 ± 0.8 ng/ml, mean ± SE, $n = 19$) and fell thereafter to <1.0 ng/ml. Zuclomiphene levels increased rapidly between 14 and 8 days before the surge (53.9 ± 2.8 ng/ml, mean ± SE, $n = 5$) and then decreased gradually but remained elevated throughout the luteal phase (29.0 ± 1.2 ng/ml, mean ± SE, $n = 33$). Late luteal endometrial histology was abnormal in one of four available treatment cycle specimens, but the endocrine characteristics and number and subcellular distribution of estrogen receptor and progesterone receptor in the abnormal cycle were not different from those of normal, in-phase cycles. Total estrogen receptor and progesterone receptor at midcycle were three to four times higher ($p < 0.01$) than in the late luteal phase in both spontaneous cycles (7.2 ± 2.3 vs 1.9 ± 0.4 pmol/mg deoxyribonucleic acid estrogen receptor and 41.3 ± 13.9 vs 13.4 ± 3.9 pmol/mg deoxyribonucleic acid progesterone receptor) and clomiphene-induced cycles (8.2 ± 2.3 vs 1.8 ± 0.8 pmol/mg deoxyribonucleic acid estrogen receptor and 40.4 ± 9.9 vs 10.1 ± 4.1 pmol/mg deoxyribonucleic acid progesterone receptor), but neither midcycle nor late luteal estrogen receptor or progesterone receptor in any category (total, cytosolic, or salt-extracted nuclear) differed from spontaneous cycle values. These data strongly suggest that clomiphene citrate treatment does not adversely affect endometrial estrogen receptor and progesterone receptor induction. (AM J OBSTET GYNECOL 1991;165:177-85.)

Key words: Clomiphene citrate, estrogen receptors, progesterone receptors, endometrium

Clomiphene citrate, a triphenylethylene compound, is the most common agent in clinical use for ovulation induction. Clomiphene citrate binds to the estrogen receptor at numerous sites throughout the reproductive system, including the hypothalamus, pituitary, ovary, endocervix, and endometrium. Its mechanism of action in ovulation induction appears to involve interference with the process of estrogen receptor replenishment at the hypothalamic level, thereby causing a central misinterpretation of circulating estrogen concentrations, the perception of a hypogonadal state, and, by altering the pattern of pulsatile gonadotropin-releasing hormone secretion, stimulation of increased pituitary gonadotropin release and enhanced follicular

6/1/28540

development. However, in addition to its desirable central actions, clomiphene citrate exerts the same antiestrogenic influence at sites in the periphery (some of which are undesirable and potentially counterproductive).

Clinically, luteal phase deficiency frequently complicates ovulation induction with clomiphene citrate.[1,2] Although the mechanism or mechanisms responsible remain unclear, many consider the problem to be an unavoidable consequence of competition between central and peripheral actions of the drug. Because luteal phase defects may result from inadequate progesterone secretion and/or a failure of endometrial response, levels of luteal phase progesterone production that are typically higher in clomiphene-induced than in spontaneous cycles, suggest that clomiphene may have direct adverse effects on the endometrium that predispose to luteal phase deficiency. The drug's inherently antiestrogenic nature further implies that clomiphene may interfere with estrogen induction of effective endometrial estrogen and progesterone receptor populations. Clearly, inadequate estrogen and/or progesterone receptor or abnormal receptor function could result in delayed, inadequate, or asynchronous endometrial development, but to date the net influence of clomiphene administration on endometrial steroid hormone receptor populations has not been clearly defined.

The extent of endometrial estrogen and progesterone receptor induction in cycles induced by clomiphene citrate must reflect the relative balance between two opposing influences. Although receptor induction in clomiphene-induced cycles may well be enhanced by typically elevated preovulatory estradiol levels, it may also be inhibited by a premature rise in circulating progesterone concentrations[3] and antagonized directly by the drug itself. Previous studies that we[4] and others[5-7] have conducted to examine this question have been inconclusive. Heretofore, attention has focused on the luteal phase endometrium, in which steroid receptor concentrations have normally already fallen substantially from peak values at midcycle.[8] All studies[4-7] have used conventional steroid-binding assay methods. Unfortunately, antiestrogens or their metabolites have demonstrated the capacity to effectively interfere with in vitro binding of radioligands to estrogen receptor.[9] Thus steroid-binding assay may not be entirely suitable for examinations of endometrial steroid receptor dynamics in clomiphene-treated patients.

In this study we have futher investigated the effect of clomiphene citrate on endometrial estrogen receptor and progesterone receptor populations. To avoid the influence of potentially confounding factors present in infertile populations, we studied normal ovulatory women, each of whom was examined in a spontaneous and clomiphene-induced cycle. To better evaluate the net influence of clomiphene treatment on endometrial development and steroid receptor induction, we examined both midcycle and late luteal endometrial tissue specimens in all cycles. To eliminate the possibility that administered antiestrogen might interfere with accurate receptor quantitation, we used an enzyme-linked immunoassay rather than a steroid-binding assay in determining estrogen receptor and progesterone receptor concentrations.

Material and methods

Subjects. Five normal parous women, aged 26 ± 3 years (mean ± SD), were recruited and gave informed consent for this study, which was approved by our institutional review board. Each woman had regular predictable menstrual cycles and had not used steroid contraception for at least 6 months before the study. The menstrual cycle of each participant was first screened by basal body temperature monitoring to eliminate possible gross ovulatory dysfunction.

Study design. Each woman was studied during two separate menstrual cycles. In the first cycle (control), venous blood samples were obtained on alternate days from cycle day 3 to 11. Beginning on day 11, a urine sample was obtained twice daily, the first between 11 AM and 3 PM and the second between 5 and 10 PM. Blood samples were drawn daily until 1 day after the urinary luteinizing hormone (LH) surge was identified via a rapid semiquantitative commercial enzyme immunoassay kit, Ovustick (Monoclonal Antibodies, Inc., Mountain View, Calif.) that uses the first international standard for menopausal gonadotropins. Thereafter, urine sampling was discontinued and blood sampling returned to alternate days until the onset of menses. An endometrial biopsy speciman was obtained from the uterine fundus with a disposable aspiration cannula (Pipelle, Unimar, Wilton, Conn.) on the day of the urinary LH surge and again 13 days later. In the second cycle blood and urine sampling and endometrial biopsy were carried out in an identical fashion, and 150 mg of clomiphene citrate (Clomid, Merrell, Cincinnati) was self-administered in a single daily dose on cycle days 5 through 9.

Venous blood samples were allowed to clot, and the separated serum was frozen at −20° C until it was assayed for estradiol, progesterone, follicle-stimulating hormone (FSH), LH, and clomiphene isomers. Representative samples of each endometrial tissue specimen were fixed in 10% formalin; the remainder of each specimen was placed in a sealable plastic envelope, immediately snap-frozen by immersion in liquid nitrogen, and stored at −80° C for determination of cytosolic and salt-extracted nuclear endometrial estrogen and progesterone receptor concentrations. Histologic sections were examined by three independent gynecologic pathologists, all using the criteria of Noyes et al.[10] and without knowledge of the experimental conditions. Each late luteal phase biopsy specimen was assigned a histologic date encompassing a 2-day interval and interpreted according to the most advanced day; the mean result was judged with reference to both the serum LH surge and onset of menses. Endometrial specimens that were ≥3 days out of phase were considered abnormal and consistent with the diagnosis of luteal phase defect.

Hormone, clomiphene, and receptor assays. Serum estradiol and progesterone concentrations were measured by specific radioimmunoassay; concentrations of FSH and LH were measured by immunoradiometric assay with commercial assay kits (Diagnostic Products, Los Angeles). To reduce interassay variability, all serum samples from the control and clomiphene treatment cycles of each individual woman were assayed together for each hormone. The intraassay and interassay coefficients of variation were <10% in all four assay systems. Detection limits were 0.12 and 0.2 mIU/ml for LH and FSH, respectively, and 8.0 pg/ml and 0.5 ng/ml for estradiol and progesterone, respectively. Gonadotropin values were expressed in international units of the first international reference preparation 68/40 for LH and the second international reference preparation of human menopausal gonadotropin for FSH. Serum concentrations of enclomiphene and zuclomiphene isomers in treatment cycles were determined by methods previously described in detail.[11] Briefly, samples were extracted with tert-butyl methyl ether, and the drug and its metabolites were separated by reversed-phase high-performance liquid chromatography. The eluent was fed into a braided or woven, cylindric Teflon reaction coil into which a low-energy mercury lamp had been inserted. The result was a photoinduced stilbene-to-phenanthrene oxidation that yielded highly fluorescent analytes that were then quantified with fluorescence spectrophotometry. The assays were performed by Hazelton Laboratories (Madison, Wis.) in affiliation with Serono Laboratories (Norwell, Mass.). Intraassay and interassay coefficients of variation were <10% for both the enclomiphene and zuclomiphene isomers.

Frozen endometrial tissue specimens were thawed on ice and homogenized (1:10, wt/vol) in TEDG-Mo buffer (0.05 mol/L Tris hydrochloride, 1.5 mmol/L sodium ethylenediaminetetraacetic acid, 0.5 mmol/L dithiothreitol, 10% glycerol, and 10 mmol/L sodium molybdate; pH 7.5) with two bursts (10 seconds) of a precooled Polytron (Brinkman Instruments, Westbury, N.Y.) at a setting of 5 with a 10-second cooling interval. Tissue homogenates and all reagents were maintained at 0° to 4° C during processing and assay. Homogenates were centrifuged at 800 *g* for 10 minutes to provide a crude nuclear pellet. To prepare the cytosol fraction, the supernatant was removed and centrifuged at 40,000 *g* for 20 minutes; it was then diluted with TEDG-Mo buffer to yield a protein concentration of 0.5 to 1.0 mg/ml as determined by the method of Lowry et al.[12] Crude nuclear pellets were washed once with TEDG-Mo buffer (5 ml), and a nuclear extract was obtained by resuspending pellets in hypertonic buffer (0.6 mol/L potassium chloride–TEDG-Mo buffer) and incubating them for 60 minutes. Before recentrifugation (40,000 *g* for 20 minutes), nuclear extracts were diluted 1:1 with TEDG-Mo buffer to yield a protein concentration in a range from 0.5 to 1.0 mg/ml. Estrogen receptor and progesterone receptor enzyme-linked immunoassay kits (Abbott Laboratories, North Chicago) were obtained, and the assays were conducted according to the manufacturer's specifications. Endometrial estrogen and progesterone receptor concentrations were expressed in picomoles per milligram of deoxyribonucleic acid after quantitation of tissue deoxyribonucleic acid content by the method of Burton.[13]

Data analysis. Hormone data for all cycles and drug data from treatment cycles were synchronized to the day of the serum LH peak (LH + 0), and significant differences in hormone concentrations between the control and clomiphene treatment cycles were determined by two-way analysis of variance (day of cycle and experimental groups) for repeated measures. Results of histologic endometrial dating were compared with the McNemar test. Receptor concentrations within and between control and treatment cycles were compared with paired *t* tests; $p < 0.05$ was considered significant.

Results

Clinical findings. Each of the menstrual cycles of all five women was ovulatory, as judged by typical biphasic basal body temperature patterns, the identification of an LH surge in both urine and serum, a postovulatory rise in serum progesterone concentrations, and the finding of secretory endometrium in the second biopsy specimen obtained in each of the studied cycles (both control and clomiphene treatment cycles. A urinary LH surge was identified in all cycles and correlated well with that in serum. In all women peak serum LH concentrations occurred on or 1 day after the day of urinary LH surge onset. As a result, midcycle endometrial biopsies in both control and clomiphene-induced cycles were performed on LH − 1 or LH + 0, and late luteal endometrial biopsy specimens were uniformly obtained on LH + 12 or LH + 13 in 9 of 10 study cycles. One patient experienced onset of menses before a scheduled late luteal biopsy after clomiphene treatment. Therefore, data derived from treatment cycle LH + 13 tissue

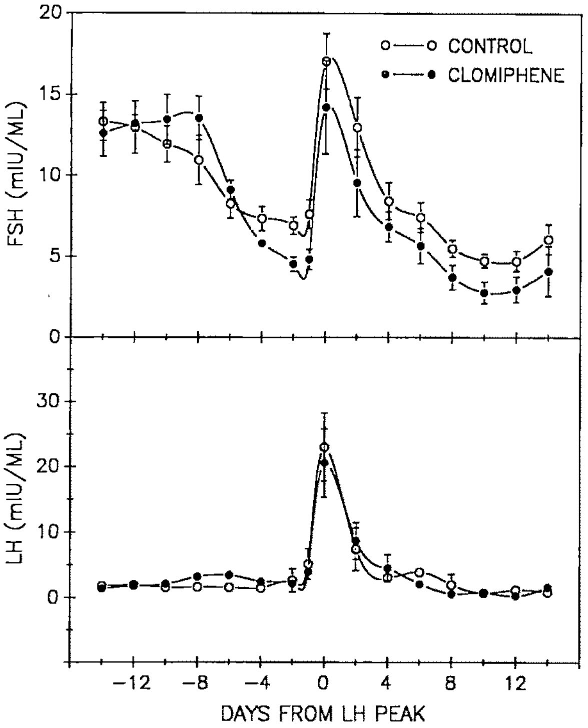

Fig. 1. Serum FSH and LH concentrations (mean ± SE) in five women during a spontaneous cycle (control) and a cycle in which they received clomiphene citrate (150 mg/d, cycle days 5 to 9). FSH values are expressed in terms of second international reference preparation human menopausal gonadotropin and those of LH in terms of the first international reference preparation 68/40.

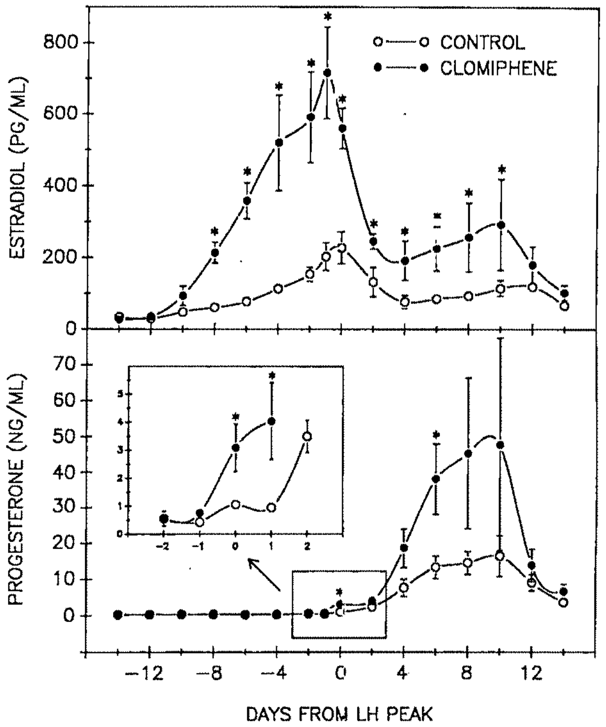

Fig. 2. Serum estradiol and progesterone concentrations (mean ± SE) in five women during a spontaneous cycle (control) and during a cycle in which they received clomiphene citrate (150 mg/day, cycle days 5 to 9). *Asterisk*, $p < 0.05$.

specimens reflect results obtained in four of the five women studied. Overall cycle length, day of LH surge, and luteal phase duration are summarized in Table I. None of these paramters in clomiphene treatment cycles was significantly different from corresponding control cycle values.

Hormone data. Serum LH and FSH concentrations in the control and clomiphene treatment cycles of the five women are shown in Fig. 1. Although midfollicular-phase FSH levels tended to be higher and luteal phase concentrations lower in clomiphene cycles, the differences were not significant. Similarly, LH levels throughout the cycle of clomiphene administration were not different from those observed in control cycles. Serum concentrations of estradiol and progesterone in control cycles and after clomiphene treatment are illustrated in Fig. 2. As expected, serum estradiol levels in clomiphene cycles were significantly higher ($p < 0.05$) than corresponding control cycle values. Estradiol concentrations remained significantly elevated throughout the interval from day LH − 8 to day LH + 10 in clomiphene cycles; levels in the follicular phase were threefold to fivefold greater than they were without clomiphene treatment. Serum progesterone concentrations were also significantly higher ($p < 0.05$) after clomiphene administration. This difference first became apparent in the periovulatory phase; significantly increased progesterone levels were observed on days LH + 0 and LH + 1. Mean serum progesterone level remained elevated throughout the luteal phase but to a widely varying extent among patients; concentrations in one individual rose as high as 166 ng/ml.

Clomiphene isomers. Serum concentrations of enclomiphene and zuclomiphene in treatment cycles are shown in Fig. 3. Enclomiphene levels rose abruptly to a plateau (4.1 ± 0.8 ng/ml, mean ± SE, $n = 19$) between day LH − 12 and day LH − 6. Thereafter, concentrations fell equally as abruptly to <1.0 ng/ml, where they remained for the rest of the cycle. In contrast, levels of zuclomiphene increased rapidly from day LH − 14 to peak on day LH − 8 (53.9 ± 2.8 ng/ml, mean ± SE, $n = 5$) and then very gradually fell until onset of the subsequent menses. The overall mean luteal phase concentration of zuclomiphene was 29.0 ± 1.2 ng/ml (mean ± SE, $n = 33$).

Receptor concentrations. Endometrial estrogen receptor concentrations are shown in Fig. 4. As we had anticipated, midcycle (day LH + 0) levels of total, cytosolic, and salt-extracted nuclear estrogen receptor were significantly higher ($p < 0.01$) than late luteal

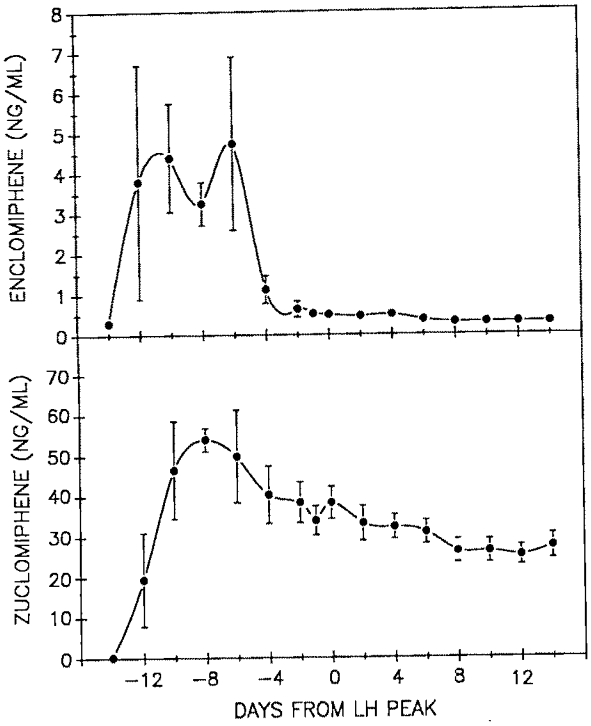

Fig. 3. Serum enclomiphene and zuclomiphene concentrations (mean ± SE) in five women during a cycle in which they received clomiphene citrate (150 mg/day, cycle days 5 to 9).

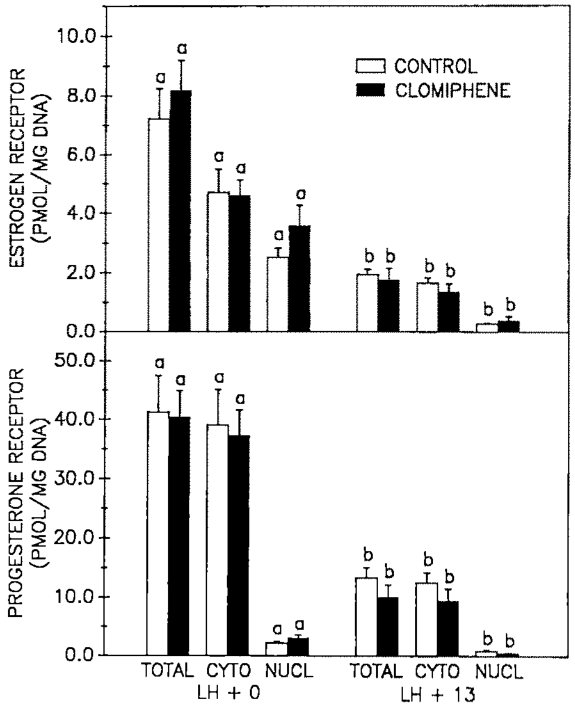

Fig. 4. Endometrial concentrations (mean ± SE) of *total*, cytosolic *(cyto)*, and salt-extracted nuclear *(nucl)* estrogen and progesterone receptor in five women during a spontaneous cycle and during a cycle in which they received clomiphene citrate (150 mg/day, cycle days 5 to 9). In each class *(total, cyto,* and *nucl) bars with different superscripts* are different ($p < 0.01$).

phase (LH + 13) values in both control and clomiphene treatment cycles. However, despite the significant sustained increase in circulating estradiol levels associated with clomiphene administration, neither midcycle nor late luteal estrogen receptor concentrations in any of the three categories differed significantly from control cycle values. In both cycles the proportion of total estrogen receptor recovered from nuclear extracts was significantly greater ($p < 0.01$) in the LH + 0 tissue specimens than in the LH + 13 biopsy specimens, but neither the midcycle luteal values nor the late luteal values were altered by the clomiphene treatment.

Immunoassayable endometrial progesterone receptor concentrations are also illustrated in Fig. 4. As was true of estrogen receptor, total, cytosolic, and salt-extracted nuclear progesterone receptor on day LH + 0 were all significantly elevated ($p < 0.01$) when compared with day LH + 13 values in both control and clomiphene treatment cycles. Again, however, both midcycle and late luteal progesterone receptor concentrations in all three categories remained unchanged after clomiphene administration. The proportion of total endometrial progesterone receptor residing within the nuclear fraction was relatively low in all tissue specimens (6.5% ± 2.6%, mean ± SE, $n = 19$) and did not vary with phase of cycle or clomiphene treatment. Despite the fact that mean periovulatory progesterone levels were significantly higher in clomiphene cycles (Fig. 2), there was no associated significant shift in the overall mean percent nuclear progesterone receptor observed between the two cycles in day LH + 0 specimens. There was, however, a tendency toward increased percent nuclear progesterone receptor in clomiphene cycle day LH + 0 tissues in those patients who had the greatest relative increases in periovulatory progesterone over the respective control cycle values.

Endometrial histology. Late luteal phase endometrial histology revealed no significant difference between control and clomiphene treatment cycles overall. All control cycle biopsy specimens and three of the four treatment cycle specimens were judged normal, whether they were evaluated with reference to the serum LH surge or to the onset of the next menses. The treatment cycle biopsy specimen in one patient was abnormal because it exhibited a maturation delay of 4 and 5 days relative to onset of menses and LH surge, respectively, but neither the endocrine characteristics nor the number and subcellular distribution of midcycle or late luteal phase endometrial estrogen or progesterone receptor in this abnormal cycle were significantly different from those values in the remaining three treatment cycles in which the histology was normal.

Table I. Cycle characteristics before and during clomiphene citrate treatment (mean ± SEM)

Characteristic	*Cycle*	
	Control	*Clomiphene*
Cycle length (days)	30.8 ± 1.3	29.8 ± 0.9
LH surge (cycle day)	17.2 ± 1.2	16.4 ± 0.8
Luteal phase duration (days)	13.6 ± 0.2	13.4 ± 0.4

Comment

Clomiphene citrate has been implicated as a cause of luteal phase deficiency and, paradoxically, also is advocated for treatment of the same disorder. Its therapeutic potential derives from luteal phase steroid hormone production that is consistently greater in clomiphene-induced than in spontaneous ovulatory cycles. The higher circulating steroid levels almost certainly result from a drug-induced increase in gonadotropin secretion, improved folliculogenesis in the single dominant follicle and/or the larger cohort of follicles recruited to participate in the treatment cycle,[14] and a subsequent increase in overall luteal cell mass. Although the drug's extended half-life may alternatively afford it the opportunity to influence corpus luteum steroidogenesis more directly, available evidence indicates that such effects, if they are exerted at all, are inhibitory in nature.[15] However, the ability of clomiphene to antagonize estrogen actions in the periphery may at the same time prevent an appropriate endometrial response to normal or even increased steroid concentrations. Because normal secretory endometrial maturation requires the combined actions of estrogen and progesterone and because both steroids exert their effects through specific estrogen-induced endometrial receptors, direct interference with estrogen induction of effective endometrial estrogen and progesterone receptor populations is one mechanism that might explain the increased incidence of luteal phase deficiency associated with clomiphene use.[1,2]

Clomiphene treatment typically increases late follicular phase serum estradiol and progesterone concentrations; both may exert significant, if opposite, influence on endometrial steroid receptor induction and thus may modify any direct antiestrogenic actions of clomiphene itself. The effect of these many competing direct and indirect clomiphene-induced changes has not been clear. Clomiphene has been shown to reduce concentrations of endometrial estrogen and progesterone receptor induced by estrogen replacement in postmenopausal women. Moreover, decreased concentrations of both receptors have been identified in late luteal phase endometrium after clomiphene induction of ovulation,[5] after continuous luteal phase clomiphene administration in normal women,[4] and in tissue specimens obtained at the time of oocyte retrieval after combined treatment with clomiphene, human menopausal gonadotropins, and human chorionic gonadotropin for in vitro fertilization.[6] Together, these data suggest that clomiphene does interfere with the induction and/or maintenance of effective endometrial steroid receptor populations. Other studies, however, deny that clomiphene has an adverse effect on the endometrium. A recent report that periimplantation phase nuclear estrogen and progesterone receptor levels and binding affinity in normal ovulatory women were no different after both low-dose (50 mg) and high-dose (150 mg) clomiphene treatment than in spontaneous cycles is of particular interest.[7] Interpretation of these conflicting data has been confounded by diversity in study populations and methodologic differences and is now further complicated by recent evidence that conventional steroid-binding assay methods used in these studies may yield inaccurate estrogen receptor determinations in tissues exposed to antiestrogens in vivo.

To clarify the effect of clomiphene on endometrial estrogen and progesterone receptor induction, we elected to examine tissue specimens that would reflect both the peak (midcycle) and nadir (late luteal phase) in receptor populations. We used a recently developed enzyme-linked immunoassay to measure total, cytosolic, and salt-extracted nuclear estrogen and progesterone receptor concentrations in endometria derived from both spontaneous and clomiphene-induced cycles in the same patients. The enzyme-linked immunoassay is based on the recognition of two distinct antigenic determinants in the receptor molecule that are distinct from the hormone-binding region and that require the presence of an intact receptor molecule for detection. The method is therefore independent of the state of receptor occupancy and applies equally well to receptor quantitation in both cytosol and nuclear fractions of tissue homogenates. Enzyme-linked immunoassay determinations of cytosolic and nuclear estrogen and progesterone receptor generally correlate well with data generated by steroid-binding assay in both normal endometrium[16] and in breast cancer tissue[9] and have been demonstrated to accurately predict the endocrine dependence of human breast cancers. However, only immunoassay detected significant levels of cytosolic estrogen receptor in breast tumor tissue from patients under treatment with tamoxifen, a potent antiestrogen[9]; steroid-binding assay failed to detect estrogen receptor in these specimens. The mechanism responsible for this discrepancy is not yet clear, but these data demonstrate the potential for steroid-binding assay to underestimate estrogen receptor in tissues of patients treated with antiestrogens.

The increase in follicular phase estradiol levels observed in treatment cycles was striking and remarkable in the absence of a distinct rise in gonadotropin secretion. Mean FSH and LH levels were indeed higher than corresponding control values during the interval of clomiphene administration, but the differences were not statistically significant, probably because the rise in each was subtle and the sample size small. The possibility remains that clomiphene administration may impair the metabolic clearance of estradiol or may result in the release of an altered form of FSH that has enhanced biologic activity, but there is no evidence to indicate that clomiphene might stimulate ovarian steroidogenesis directly.[15] The increase in estradiol production after clomiphene treatment probably reflects the recruitment of additional follicles more than increased estrogen synthesis in the dominant follicle already selected.[14] Regrettably, however, we did not monitor follicular development with serial ultrasonography in this study, and we acknowledge that the mechanism responsible for the marked rise in estradiol levels requires additional investigation.

As anticipated, the concentrations of total, cytosolic, and salt-extracted nuclear estrogen and progesterone receptor were markedly higher at midcycle than during the late luteal phase. These findings are consistent with earlier studies[8] and reflect the largely unopposed influence of estrogen on estrogen and progesterone receptor induction during the follicular phase of the menstrual cycle. Despite an approximately threefold increase in circulating estradiol levels after clomiphene administration, no significant net change in the concentration of estrogen or progesterone receptor in any category was observed in treatment cycles. The failure of elevated estradiol to induce increased concentrations of endometrial estrogen and progesterone receptor at midcycle may result from the inhibition of circulating clomiphene and/or the premature periovulatory rise in serum progesterone, because progesterone inhibits estrogen receptor production and, indirectly, the induction of its own receptor. Alternatively, already maximal concentrations of endometrial estrogen and progesterone receptor may be induced by normal ovulatory threshold levels of estradiol, and elevated estrogens may, conversely, buffer an otherwise inevitable decline in receptor levels caused by clomiphene and/or elevated progesterone. Our data are in general agreement with those of Hecht et al.[7] in a recent study of midluteal phase endometrium that uses a similar design. Their somewhat lower absolute levels of receptor may be attributed to the use of crude nuclear suspensions and elevated incubation temperatures (which are characteristic of steroid-binding assay) that may lead to underestimation of nuclear steroid receptor content, in contrast to our use of high-salt nuclear extracts and enzyme-linked immunoassay. Although we observed no change in the number and subcellular distribution of estrogen and progesterone receptor in whole endometrium after clomiphene treatment, a shift in the distribution of estrogen and progesterone receptor between the stromal and glandular compartments may have occurred and gone unrecognized. Complex and dyssynchronous fluctuations in the secretory phase progesterone receptor content of endometrial glands and stroma have recently been demonstrated.[17] Such changes would not be detected by enzyme-linked immunoassay and could be demonstrated only by an immunocytochemical approach to steroid receptor detection.

The late luteal phase endometrial histology was normal in three of four available treatment cycle specimens, exhibited a clinically significant maturation delay consistent with luteal phase deficiency in one individual, and was not evaluated in another patient because of the early onset of menses. The endocrine characteristics and number and subcellular distribution of endometrial estrogen and progesterone receptor in the abnormal cycle were indistinguishable from those of in-phase cycles. Although the number of individuals studied is small, these data clearly argue against drug-induced disruption of endometrial steroid receptor induction as the mechanism of luteal phase deficiency associated with the administration of clomiphene citrate. Nevertheless, the clincial relevance of our findings in normal ovulatory women may be questioned because numerous studies of endometrial steroid receptor levels have failed to establish inadequate or dysfunctional receptors as a cause of luteal phase deficiency and because the link drawn between clomiphene treatment and the increased risk of luteal phase inadequacy derives from observations made in anovulatory infertile patients undergoing long-term therapy.

The widely varying estrogen and progesterone receptor content of endometrial tissue derived from infertile women with spontaneous luteal phase defects probably reflects only the many and varied mechanisms that may cause luteal phase inadequacy, as well as the unavoidable study of etiologically diverse populations within and between such studies. In any case the lack of a characteristic endometrial steroid receptor profile in luteal phase deficiency does not exclude altered receptor dynamics as a cause of the disorder. However, the relative endocrine impact of experimental acute clomiphene administration in normal women may indeed significantly differ from that in anovulatory individuals who receive continuous treatment. The extent to which the estrogen agonistic and antagonistic actions of clomiphene isomers are expressed may vary with dose, duration of therapy, and the differing endocrine milieus of normal and anovulatory women. The extended half-life of clomiphene and its corresponding potential for significant systemic accumulation have been demonstrated. Even in our isolated treatment cycle, we observed a striking, sustained elevation of serum zuclomiphene throughout the luteal phase. Circulating concentrations that are higher still almost certainly exist in patients who fail to conceive promptly and who therefore continue treatment for extended periods of time. Therefore dose- and time-dependent adverse effects of clomiphene on endometrial steroid receptor populations cannot be excluded, in spite of the use of high-dose clomiphene in this study and in other studies that have failed to demonstrate such an effect.

If clomiphene treatment does, in fact, predispose to an increased risk of luteal phase deficiency, mechanisms that are unrelated to endometrial steroid receptor concentrations and/or function are likely to be involved. These mechanisms may be unique to clomiphene cycles or they may be similar to those that operate in women with spontaneous luteal phase defects. Direct adverse endometrial effects of clomiphene that operate through post-receptor mechanisms remain a possibility. The occasional marked elevation of luteal phase estradiol that follows clomiphene-induced ovulation may directly interfere with endometrial decidualization,[18] and there is evidence that clomiphene may directly inhibit corpus luteum steroidogenesis.[15] Second, inadequate luteal function is often only a natural consequence of similarly inadequate folliculogenesis; luteal phase deficiency consistently accompanies follicular phase FSH deficiency that is spontaneous or experimentally induced. Because clomiphene induction of ovulation is an empiric incremental titration in which success depends on the extent of induced pituitary FSH release, clomiphene-associated luteal phase deficiency may at times reflect only inadequate treatment rather than a specific deleterious action of the drug itself. An abnormally increased follicular phase LH pulse frequency is a subtle aberration of gonadotropin secretion that is also implicated in the pathogenesis of luteal phase defects.[19] Interestingly, clomiphene appears to induce a similar increase in LH pulse frequency which presumably reflects an increase in pulsatile hypothalamic gonadotropin-releasing hormone secretion.[20] Excess clomiphene, whether it results from frank overdosage or accumulation after long-term administration, may provoke an abnormally rapid pattern of gonadotropin secretion that predisposes to inadequate corpus luteum function. Regardless of the mechanism involved, the potential for luteal phase deficiency to accompany either too much or too little drug suggests that the effective therapeutic range for clomiphene may be narrower than that previously appreciated, at least in some individuals.

In summary, clomiphene citrate treatment (150 mg) did not affect concentrations of immunoassayable midcycle or late luteal phase endometrial estrogen receptor and progesterone receptor in normal ovulatory women. Although an adverse effect of low-dose or long-term clomiphene citrate administration cannot be excluded, these data refute a drug-induced disruption of endometrial steroid receptor induction as the mechanism of luteal phase deficiency associated with clomiphene citrate.

We thank Dr. Vinod Chungi (Serono Laboratories, Inc., Norwell, Mass.) and Mr. Jerry Brisson (Hazleton Laboratories, Madison, Wis.) for their generous assistance and support in providing serum assays of clomiphene isomers, and Unimar, Inc. (Wilton, Conn.) for providing the Pipelle aspiration cannulas used in this study.

The effect of the inhibition of prostaglandin synthesis on renal blood flow in fetal sheep

Susan A. Arnold-Aldea, MD, Ron A. Auslender, MD, and Julian T. Parer, MD, PhD
San Francisco, California

Treatment with prostaglandin synthesis inhibitors has been associated with oligohydramnios in the fetus. The presumed mechanism is a reduction in fetal renal blood flow. We examined the effect of meclofenamate administration on renal blood flow in chronically catheterized fetal sheep during normoxia and during moderate and severe hypoxia. Ten fetal sheep were made hypoxic twice at least 4 days after surgery: once in the presence and once in the absence of meclofenamate infusion. Renal blood flow and combined ventricular output were measured with radioactive microspheres. Prostaglandin synthesis blockade with meclofenamate caused no significant change in blood pressure, combined ventricular output, renal blood flow, or renal vascular resistance in either the normoxic or hypoxic animals. These data challenge the contention that prostaglandin activity protects the renal vascular bed of the fetus from vasoconstriction during hypoxia and they also do not support the hypothesis that prostaglandin synthesis inhibition causes oligohydramnios through reduction of fetal renal blood flow. (AM J OBSTET GYNECOL 1991;165:185-90.)

Key words: Fetal renal blood flow, prostaglandin synthetase inhibitors, meclofenamate, fetal hypoxia, fetal sheep

Prostaglandin synthetase inhibitors have emerged as useful agents in the therapy of preterm labor.[1-3] In spite of their tocolytic efficacy and ease of administration, widespread clinical use has been limited by fetal side effects. Oligohydramnios has developed in as many as 50% of patients treated with prostaglandin synthetase inhibitors.[4-5]

Prostaglandin synthetase inhibitors are known to decrease fetal urine output[6] and thereby lead to oligo-

hydramnios. This decrease in fetal urine output may result from either a decrease in fetal renal blood flow or an increase in tubular free water reabsorption. Some have reported that prostaglandin synthetase inhibitors reduce basal renal blood flow.[7] Others, however, demonstrated a decrease in renal blood flow only during status of high circulating norepinephrine, α-adrenergic neural stimuli, or elevated angiotensin II, as seen with fetal hypoxia or hypotension.[8-11]

To test the hypothesis that prostaglandin inhibition causes a decrease in fetal renal blood flow, we assessed the effect of prolonged fetal administration of meclofenamate, a prostaglandin synthesis inhibitor, on basal renal blood flow and on renal blood flow during moderate and severe hypoxia in a chronically catheterized sheep model.

Material and methods

We studied 10 fetal sheep at 125 to 130 days' gestation, products of Western Breed ewes and Black face rams. The animals were studied in accordance with the Guiding Principles for Research Involving Animals and Human Beings of the American Physiological Society.

Surgical preparation. Fasted pregnant ewes were sedated with intramuscular ketamine hydrochloride (8 mg/kg), intubated, and given halothane to induce general anesthesia. Polyvinyl catheters of 2.3 mm external diameter were inserted into the maternal femoral vein and artery and advanced into the inferior vena cava and aorta. The uterus was exposed through a ventral midline incision. The fetal hind limbs were delivered through a small hysterotomy and catheters with a 1.2 mm external diameter were inserted into the pedal artery and vein and advanced into the inferior vena cava and aorta. Through a separate hysterotomy, both front limbs were delivered and catheters of 1.2 mm external diameter were inserted into the axillary artery and advanced into the ascending aorta. An open-ended catheter was sutured into the intrauterine cavity and filled with saline solution for measurement of amniotic fluid pressure. The vascular catheters were filled with heparin sulfate solution (1000 U/ml). Intramuscular dihydrostreptomycin (1.25 gm), and intravenous procaine penicillin G (1 million U) were administered to the ewe on the day of surgery and on each postoperative day.

Measurements. Maternal arterial and fetal arterial blood pressure levels and amniotic fluid pressure were recorded continuously with pressure transducers (P23Db, Statham, Oxnard, Calif.). Fetal blood pressure was corrected for amniotic fluid pressure, which was used as the zero reference pressure. Maternal heart rate was determined from the tracing of pulsatile blood pressure. Fetal heart rate was recorded with a cardiotachometer. Blood values, pH, oxygen saturation and hemoglobin concentration were measured on a blood gas monitor (HM 73, Radiometer, Copenhagen) and OSM2 hemoximeter (Radiometer).

Fetal combined ventricular output and renal blood flow values were determined with the radionuclide-labeled microsphere method.[12] Microspheres 15 μm in diameter were injected into the inferior vena cava while reference blood samples were withdrawn from the ascending and distal aorta at a rate of 3.8 ml/min. The microspheres were labeled with the following radionuclides: gadolinium 153, cobalt 57, indium 114, chromium 51, stannum 113, strontium 85, niobium 95, zinc 65, or manganese 54 (3-M Company, St. Paul, Minnesota). After each microsphere injection, withdrawn fetal blood was replaced with 15 ml of heparinized maternal blood collected at the beginning of the experiment.

At the conclusion of the study, the ewes were killed with a rapid intravenous injection of sodium pentobarbital and 3 mol/L potassium chloride. The fetus was removed and weighed. The fetal organs were dissected, weighed, ashed, and powdered as previously described.[12] Radioactivity was counted in a 1000-channel computerized pulse height analyzer (Ino-Tech Inc., Wisconsin).

Vascular resistance estimation was obtained by dividing the arterial-venous pressure difference by the renal blood flow. Central venous pressure was not measured in these animals but assumed to be constant at 3 mm Hg as shown by previous studies.[13]

Experimental protocol. The animals were studied 3 to 6 days after surgery. Data were recorded from the mother and the fetus while the ewe stood quietly in a study cage. Each fetus was studied twice. One of the

studies consisted of measuring the fetal response to hypoxia alone, whereas the other study consisted of measuring the fetal response to hypoxia after pretreatment with a prolonged infusion of meclofenamate. To eliminate the possible effect of experimental deterioration over time the order of studies was randomly assigned. In two animals hypoxia alone was preceded by infusion of the carrier solution without the meclofenamate to exclude an effect of the carrier as well as the volume load on fetal cardiac output and blood flow distribution.

The hypoxic study consisted of a control period of 20 minutes followed by a period of hypoxia. The duration of hypoxia necessary to cause severe hypoxia (defined as Ca_{O_2} <1.0 mml^{-1}) varied from animal to animal (range, 20 to 35 minutes). Fetal hypoxia was induced by placing the head of the ewe in a clear plastic bag and administering an oxygen-poor gas mixture of air, nitrogen, and carbon dioxide. The maternal P_{CO_2} was kept constant by adjusting the amount of inspired carbon dioxide. During the experiment, maternal blood and amniotic fluid pressure and heart rate and fetal blood pressure and heart rate were measured continuously. Fetal cardiac output and blood flow distribution were measured at the end of the control period and three times during the hypoxia period when the fetal ascending aortic oxygen content was measured to be between 1.5 and 1.8 mml^{-1}, 1.0, and 1.5 mml^{-1} and <1.0 mml^{-1}. Blood gas values, pH, oxygen saturation, and hemoglobin measurements were done on blood samples from the maternal aorta and from the fetal ascending aorta and inferior vena cava before and after each blood flow determination.

The meclofenamate study consisted of a control period of 20 minutes, a drug infusion period of 4 hours, and a period of hypoxia. The duration of hypoxia necessary to cause severe hypoxia (defined as Ca_{O_2} <1.0 mm^{-1}) varied from animal to animal and ranged between 15 and 35 minutes. Meclofenamate (50 mg) was dissolved with 2 ml of 0.715% sodium carbonate and diluted with 40 ml of distilled water and 60 ml of normal saline solution. Meclofenamate was administered with an initial bolus of 20 mg (approximately 6 mg/kg fetal weight) given over 10 minutes, followed by a 4-hour infusion at a dose of 1.15 mg/hr (approximately 0.3 mg/kg fetal weight).

During the experiment, maternal blood pressure, amniotic fluid pressure, and heart rate and fetal blood pressure and heart rate were measured continuously. Fetal cardiac output and blood flow distribution were measured at the end of the control period, after the 4 hours of meclofenamate infusion, and three times during the hypoxia period when the fetal oxygen content was measured as between 1.5 and 1.8 mml^{-1}, 1.0 and 1.5 mml^{-1}, and <1.0 mml^{-1}. Blood gas values, pH, oxygen saturation, and hemoglobin measurements were done on blood samples from the maternal aorta and from the fetal ascending aorta and inferior vena cava before and after each blood flow determination.

Analysis of data. To reduce the effect of interanimal variability the data are also expressed as percentage of control, where each animal serves as its own control.

All values in text, tables, and figures are means ± SEM. Statistical analysis was performed with one-way analysis of variance. When the data were found to be asymmetric the Mann-Whitney test was used. A difference was considered significant when the p value was less than 0.05.

Results

Fetal response to meclofenamate infusion. Four-hour infusion of meclofenamate did not produce a significant change in blood gas values, blood pressure, combined ventricular output, renal blood flow, or calculated renal vascular resistance as shown in Tables I and II. To verify that interanimal variability had not masked a positive result, each animal was used as its own control. Renal blood flow expressed as percentage of control and percentage of cardiac output also failed to show a significant change after meclofenamate infusion.

Response to hypoxemia. The administration of

oxygen-poor gas mixture caused fetal Po_2, pH, and base excess to fall, whereas Pco_2 did not show any significant change during hypoxia both with and without meclofenamate pretreatment (Table III). These results suggest that our experimental approach allowed us to expose the fetus to a selective hypoxic insult. There were two degrees of hypoxia that were comparable in all animals, a milder one associated with oxygen content between 1 and 1.5 mmol/L and a more severe one associated with oxygen content <1 mmol/L.

Hypoxia did not induce significant changes in fetal arterial pressures, whereas fetal heart rate showed a statistically insignificant decline with mild hypoxia and a significant decline of 18% with severe hypoxia (Table III).

The effect of mild and severe hypoxia on combined cardiac output and renal blood flow are shown in Table III and in Fig. 1. In Fig. 2, blood flows are expressed as percentage of control to account for the marked interanimal variability. Severe hypoxia caused a significant fall in both combined ventricular output and renal blood flow.

Fetal response to hypoxemia during meclofenamate infusion. As seen in Table III, prolonged pretreatment with meclofenamate did not alter the fetal blood pressure or combined ventricular output response to moderate and severe hypoxia when compared with hypoxia alone. Whereas pretreatment with meclofenamate decreased renal blood flow during moderate and severe hypoxia as compared with hypoxia alone, the differ-

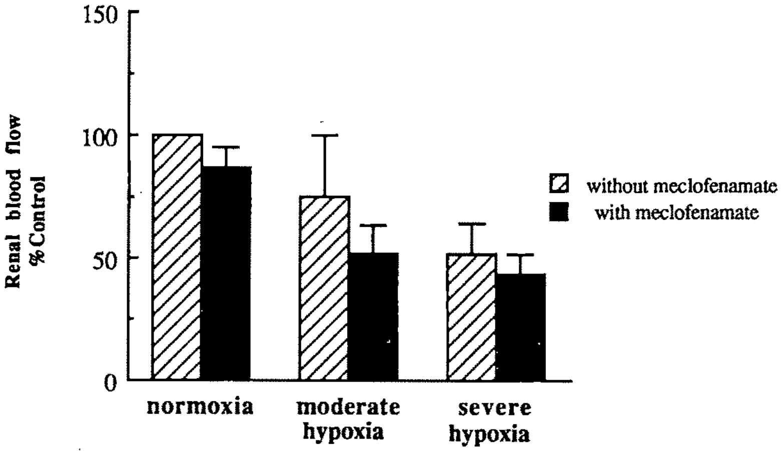

Fig. 2. To minimize interanimal variability each animal was used as its own control. The renal blood flow expressed as percentage of control shows that meclofenamate treatment did not cause a significant change in blood flow as compared to hypoxia alone. Mean ± SEM.

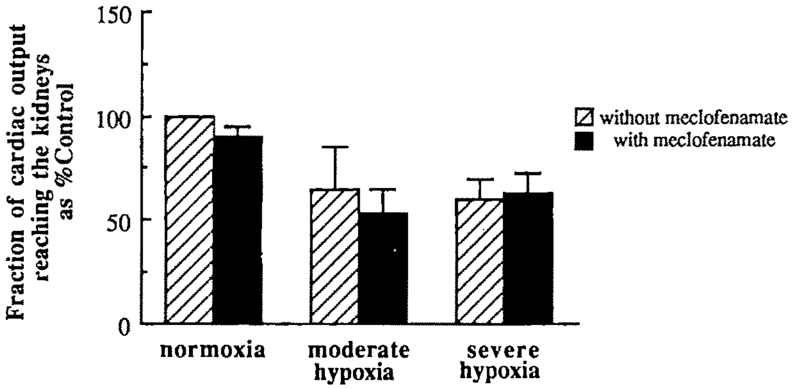

Fig. 3. When renal blood flow was expressed as the fraction of cardiac output perfusing the kidney, meclofenamate treatment did not cause a significant change in this measure as compared with hypoxia alone. Mean ± SEM.

ences did not reach statistical significance, as seen in Fig. 1. To decrease the effect of interanimal variability the results in Fig. 2 were expressed as percentage of control and in Fig. 3 renal blood flow is expressed as percentage of combined ventricular output. Again, no statistically significant effect of meclofenamate pretreatment on the response of renal blood flow to moderate and severe hypoxia could be demonstrated.

Comment

The results of this study demonstrate that prolonged treatment with meclofenamate does not significantly alter basal renal blood flow in fetal sheep. These data are in accordance with those of Rudolph et al. that showed no change in renal blood flow when either prostaglandins or inhibitors of their synthesis are administered to fetal lambs.[14, 15] Apparent discrepancies between our data and those of earlier studies may be a result of study design. Millard et al.[9] showed a reduction in renal blood flow after administration of their indomethacin or meclofenamate. Thirty minutes after the intravenous injection of either indomethacin or meclofenamate renal blood flow, as seen in the electromagnetic flow recordings, had returned to control levels, suggesting that the effect on renal blood flow was transient. To avoid studying such transient and short-lived responses, we chose to study the effect of meclofenamate on renal blood flow after a continuous 4-hour infusion of the drug.

Fetal breathing provides a sensitive and unique measure of prostaglandin activity. We therefore maximized the peripheral action of meclofenamate by choosing an administration protocol known to cause both maximal fetal ventilatory activation and supression of prostaglandin E_2 serum cocentration. In particular, Hohimer et al. have demonstrated that meclofenamate starts to cause its maximal effect on fetal ventilation after 3 to 4 hours of infusion.[16] The dosage of meclofenamate that we used was the same as that used in previous studies and known to inhibit prostaglandin synthesis in the rabbit heart[17] and to decrease plasma prostaglandin E_2 in fetal sheep.[18]

In our experiments, severe hypoxia caused a significant decrease of renal blood flow. Meclofenamate pretreatment did not significantly further the decrease in renal blood flow seen with hypoxia alone. Whereas it is possible that with a larger number of animals the effects of meclofenamate on renal blood flow could become statistically significant, in no case did we see a fall in blood flow >20%. Our data support the conclusion that steady state prostaglandin synthesis inhibition with meclofenamate does not significantly modify the renal blood flow response to moderate or severe hypoxia.

We conclude that in the chronically catheterized fetal sheep prolonged meclofenamate infusion does not significantly alter basal or hypoxic renal blood flow.

We suggest that the oligohydramnios seen in human pregnancies could be better explained by an endocrine rather than a renovascular effect of prostaglandin synthesis inhibitors. In particular, prostaglandins are thought to play an important role in the mediation of renin release, augmentation of the angiotensin II–stimulated aldosterone release from the adrenal gland, and promotion of a state of relative renal insensitivity to the antidiuretic effect of circulating arginine vasopressin.[19, 20] Prostaglandin synthesis inhibitors could increase free water reabsorption by augmenting the antidiuretic action of arginine vasopressin.[19] Clinical observations suggest that the severity of oligohydramnios is unrelated to the length of treatment, is not associated with evidence of intrauterine hypoxia, and is easily and quickly reversible.[5] These observations, like our data, are more consistent with an endocrine mechanism rather than a cardiovascular one for the occurrence of oligohydramnios.

Isolation and purification of microvascular endothelium from human decidual tissue in the late phase of pregancy

Eileen D.M. Gallery, MD,[a, b] Janet Rowe, BSc,[a] Leslie Schrieber, MD,[c] and Christopher J. Jackson, MAppSc[c]
St. Leonards, New South Wales, Australia

Normal pregnancy demands significant structural and physiologic adaptations of the uterine microvasculature, to facilitate adequate placentation. In pregnancies complicated by pregnancy-associated hypertension (preeclampsia), this process is defective, resulting in a high incidence of intrauterine growth retardation. The microvascular endothelium, a focal point for both initiation and inhibition of coagulation and control of vascular tone, may well contribute to development and aggravation of these abnormalities. We describe a method for isolation, purification, and culture of human decidual endothelial cells from biopsies performed at the time of cesarean section. The separation procedure is technically simple, requires only a small piece of tissue, and takes approximately 2 hours to perform. Some of the unique features of these cells in culture are outlined. This technique will permit the close examination of various aspects of the function of these cells in normal pregnancy, and their comparison with cells from pregnancies complicated by hypertension. (AM J OBSTET GYNECOL 1991;165:191-6.)

Key words: Decidua, endothelium, cell culture, human pregnancy

Pregnancy-associated hypertension (preeclampsia) is a common problem, associated with considerable maternal and perinatal morbidity, and characterized by dysfunction in many organs, most if not all of the clinical abnormalities explicable on the basis of disordered coagulation and vasoconstriction in many vascular beds, with resultant diminution in perfusion. In this condition, many changes have been described in both maternal intrauterine and placental vessels, although sampling probems have been encountered by many authors in the study of the placental bed.[1] It is generally agreed that there is relative failure of the expected migration of trophoblastic cells and alteration of maternal endothelial and musculoelastic tissue.[2] In addition, the uterine decidual and basal vessels display fibrin deposition, intramural accumulation of fat-laden macrophages, and a perivascular mononuclear cell infiltrate.[3] The initiating events for these abnormalities have never been fully elucidated. According to both Fox[4] and Nesbitt,[5] reduced uteroplacental blood flow[6, 7] is sufficient to cause virtually all the abnormalites seen in the placenta in preeclampsia, including the excess frequency of thrombi, fibrin deposition, and infarction in the placental circulation.[8] Ultrastructural endothelial cell damage has been described in decidual tissue both adjacent to and distant from the placental bed site.[1]

A disturbance in endothelial cell function could well contribute to the pathogenesis of the clinical syndrome of preeclampsia.[9] The vascular endothelium can provide a focal point for the initiation of processes inhibiting and promoting activation of coagulation.[10] It is also recognized as an important functional unit involved in the regulation of smooth muscle tone,[11] and is capable of producing both vasodilator and vasoconstrictor substances. Microvascular endothelium derived from different organs displays distinctive tissue-specific characteristics.[12, 13] As the most significant physiologic adaptations in the maternal microvasculature (and their abnormalites) are seen at the maternofetal interface, examination in vitro of endothelial cell function from this site is important.

An essential first step in the examination of decidual endothelial cell function is their isolation and culture. This article describes a method to isolate decidual endothelial cells with the use of dynabeads coated with the lectin UEA 1, which binds specifically to human endothelial cells by means of a cell surface glycoprotein that contains L-fucose residues.[14] Preliminary results of the growth characteristics of isolated decidual endothelial cells are also presented.

Material and methods

Subjects. The subjects were normotensive, multiparous women undergoing elective repeat cesarean section delivery for obstetric indications. The study re-

ceived prior approval from the Medical Research Ethics Committee of the Royal North Shore Hospital and Northern Sydney Area Health Service. For this preliminary study, informed verbal consent was obtained from subjects before delivery of infants.

Isolation and culture of decidual endothelium. A shallow decidual biopsy specimen was taken by the obstetrician after delivery of the placenta and was immediately placed in cold calcium- and magnesium-free Hanks' buffered salt solution (Cytosystems, Sydney, Australia). Endothelial cells were isolated as described in detail previously for the isolation of synovial endothelium.[15] Sterile procedures were used throughout. Briefly, the specimen was cut into 5 mm cubes and incubated at 37° C for 7 to 8 minutes in trypsin 1:250 (0.12 gm/dl; ICN Biomedicals, Cleveland) and Pronase (0.08 gm/dl; Calbiochem, San Diego). The resultant fragments were washed five times with Hanks' balanced salt solution, capillary segments were squeezed from the cut edges by downward pressure with the flat edge of a scalpel blade and the resultant mixed cell population was collected, centrifuged (1000 *g*, 5 minutes) and resuspended in 80 μl of Hanks' balanced salt solution plus 5% fetal calf serum. This cell suspension was incubated at 4° C for 10 minutes with 20 μl of the lectin ulex europaeus I (UEA 1)–coated dynabeads (4 × 10^8 beads/ml), as described previously,[15] and then washed five times with 2 ml Hanks' balanced salt solution plus 5% fetal calf serum, separation after each wash being achieved in a magnetic particle concentrator. In some subjects, the cell-bead complex was dissociated by competitive binding of L-fucose before plating down.

The contaminating cells contained in the wash medium and the cells attached to the beads were resuspended separately in growth medium and plated down on a gelatin-coated 35 mm tissue culture dish (Lux, Flow Laboratories). Cells were routinely maintained in a humidified incubator at 37° C in a 95% air, 5% carbon dioxide atmosphere. The growth medium used was Wissler's:McCoy's (1:1) medium containing growth factors 0.1 mg/ml endothelial cell growth supplement (Collaborative Research, Bedford, Mass.), 0.1 mg/ml heparin (Sigma Chemical, St. Louis), 2.5 μg/ml fungizone, 100 mU/ml penicillin, and 100 μg/ml streptomycin, with 40% serum: fetal calf serum, pooled human umbilical cord serum, pooled human serum from nonpregnant donors, or pooled serum collected from women in the second trimester of pregnancy (human pregnancy serum).

Cells were examined by phase contrast microscopy, refed at 2-day intervals, and passaged at confluence with the use of trypsin 1:250 (Difco, Detroit) 0.05%/0.02% (weight/volume) ethylenediaminetetraacetic acid in phosphate-buffered saline solution. Endothelium was identified by its expression of von Willebrand factor antigen with immunofluorescence.[16, 17]

Other cell lines. Human umbilical vein endothelial cells obtained from fresh umbilical cords by the method of Jaffe et al.[18] and used as a control cell population for decidual endothelial cell replication experiments, were a gift from Mr. T. To, Sutton Laboratory, Royal North Shore Hospital.

Cell replication. Cell replication experiments were conducted in triplicate by the method of Oliver et al.[19] Cells (passage 4) were plated into 96-welled plates (0.6 to 1.0 × 10^4 cells/well) in Wissler's:McCoy's medium (1:1) with endothelial cell growth supplement, heparin,

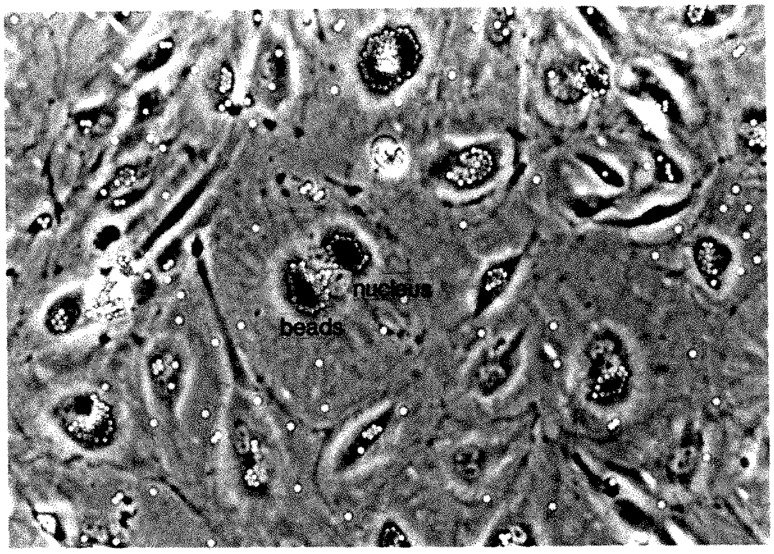

Fig. 2. UEA I–coated dynabeads bound to decidual endothelial cells in culture. A dividing cell is marked, showing the two nuclei free of beads, whereas the cytoplasm is densely covered by them. (Day 3 of primary culture, original magnification ×260).

and 10% to 40% fetal calf serum or human pregnancy serum. The effects of 40% serum without additional growth factors, and of estradiol (Steraloids, Wilton, N.H.) (at final concentrations of 50 and 500 ng/ml) were also assessed, as was the effect of doubling the media concentration of endothelial cell growth supplement in the presence of 40% fetal calf serum. After 2 or 4 days' incubation in these media, cells were washed twice with 0.9% sodium chloride, fixed in 10% formol saline solution, and stained with methylene blue (1.0 gm/dl). The plates were washed four times with 0.01 mol/L borate buffer (pH 8.5), the dye was then eluted with 1 : 1 (vol/vol) ethanol/0.1 mol/L hydrochloric acid and the optical density (OD) was read at 620 nm in a plate reader.

Results

Endothelial cells with >99% purity were obtained from 11 of 13 biopsy specimens. Within 24 hours of isolation, cells with beads bound to them had typical endothelial morphology and had formed discrete rounded colonies. By 8 days of primary culture, they formed a typical confluent cobblestone-like monolayer (Fig. 1) with the beads still attached, although the number per cell was decreased. In no instance was there overgrowth by contaminating cells. Cells that had previously been dissociated from the beads with L-fucose were indistinguishable in morphology and growth pattern in culture from those that had not been subjected to this procedure (data not shown).

In addition to their typical morphology, these cells were identified as endothelial by: (1) their expression of receptors that bind UEA I (Fig. 2); and (2) their expression of von Willebrand factor antigen, as measured by indirect immunofluorescence (Fig. 3). By light microscopy, UEA I–coated beads were bound to all cells initially isolated as endothelial, the number varying between 1 and 80, with a median of nine beads per cell. Binding to the cell membrane did not occur directly over the nucleus, a feature noted previously with human umbilical vein endothelial and synovial endothelial cells.[15] Those cells collected in the wash that had not bound to the UEA I–coated beads were a mixed population, predominantly comprising fibroblast-like cells.

Cell proliferation

General. In initial experiments, decidual endothelial cells plated down in growth medium containing 40% fetal calf serum, 40% human cord serum, or 40% pooled human serum from nonpregnant donors grew very slowly. Those whose culture medium contained 40% pooled serum collected from normal women in the second trimester of pregnancy had the most rapid growth and replication rate. With this medium, cells have been successfully grown for up to 7 passages.*[1] After an inital period of rapid growth, subculture has been possible every 18 to 22 days. During this time, the morphology of the cells has remained unchanged.

Effect of serum on cell replication. The effect of a range of concentrations (10% to 40%) of fetal calf serum or human pregnancy serum on the replication rate of decidual endothelial cells was examined at passage 4. In Fig. 4, results are shown for day 2 of a typical replication experiment. As expected, no significant change in

growth rate was observed with the addition of fetal calf serum to the growth medium over this range. By contrast, the addition of human pregnancy serum (Fig. 4, *a*) was associated with a concentration-dependent increase in cell replication.

Human umbilical vein endothelial cells at the same passage responded differently from decidual endothelial cells (Fig. 4, *b*). An increase in the concentration of fetal calf serum from 10% to 40% resulted in an increase in the replication rate (OD 0.142 U vs OD 0.295). There was a similar concentration-dependent increase in growth rate in response to human pregnancy serum, but from a substantially higher baseline value (OD 0.323), indicating greater augmentation of growth, even at human pregnancy serum concentrations as low as 10%.

Human pregnancy serum stimulated the growth of large-vessel human umbilical vein endothelial cells to a greater extent than that of decidual cells. This difference was most marked in wells with the lowest concentration of human pregnancy serum (10%) (decidual cells mean OD 0.183 vs. human umbilical vein endothelial cells OD 0.323, $p < 0.02$). Whereas the trend was similar in the presence of higher concentrations of human pregnancy serum, the difference was less marked in the presence of 40% serum (mean OD 0.418 vs. 0.465) and failed to reach statistical significance after 2 days. However, at day 4 there was a more clear-cut

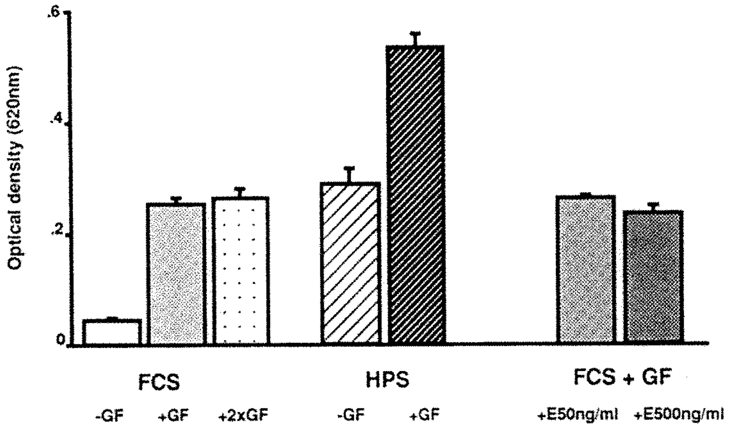

Fig. 5. Factors influencing decidual endothelial cell growth rate. Day 4 results (mean ± SD) are given for a representative experiment. (*HPS*, Human pregnancy serum; *FCS*, fetal calf serum; *E*, estradiol; *GF*, growth factors; *2 × GF*, double endothelial cell growth supplement dose).

difference between the two cell populations at this concentration of human pregnancy serum (decidual cells OD 0.527 ± 0.029 vs. human umbilical vein endothelial cells OD 0.900 ± 0.028, $p < 0.01$).

Nature of growth factor in human pregnancy serum. To examine the nature of the growth factor in human pregnancy serum a little further, we compared its effect on decidual endothelial cells (passage 4) with the growth factors endothelial cell growth supplement and heparin. Results are shown in Fig. 5. Decidual cells incubated in fetal calf serum without growth factors failed to replicate, whereas the addition of growth factors augmented levels to those seen with human pregnancy serum alone. Doubling the dose of growth factors did not stimulate more cell growth. Human pregnancy serum combined with growth factors, however, resulted in a higher cell replication rate than either stimulus alone.

Estrogen, secreted in greatly increased amounts in normal pregnancy, is a significant trophic hormone, and is one candidate for the role of the additional growth factor in human pregnancy serum. The effect of supplementation of the fetal calf serum medium with growth factors by estrogen is shown in Fig. 5. Estradiol, the major estrogen metabolite circulating in pregnancy, was added at two concentrations, 50 ng/ml (within the range of normal plasma estradiol in pregnancy) and 500 ng/ml. As shown in Fig. 5, neither of these concentrations of estradiol was associated with an increase in replication rate.

Comment

The primary goal of the experiments described here was to isolate and culture endothelial cells from late human pregnancy decidual tissue. This has been achieved: a pure population of viable cells that is von Willebrand factor-positive has been obtained with the morphologic features and growth pattern typical of endothelial cells.[16, 17] These cells have been maintained in culture for prolonged periods of time, and retain typical endothelial morphology.

Endothelial cells from different tissue sources are known to have different phenotypic characteristics.[12, 13] Our experiments have shown that decidual microvascular endothelial cells have different growth requirements from a control large vessel endothelial cell population (human umbilical vein endothelial cells). They grow more slowly. This finding has been noted for other microvascular beds.[20] They also have different nutrient requirements. A previous brief report[21] mentions an effect of human pregnancy serum in reducing the requirement of skin microvascular endothelial cells for a high concentration of human serum, suggesting the presence of a powerful growth factor. Our results confirm and extend that observation. A number of factors are known to stimulate endothleial cell growth. We have shown that the effect of human pregnancy serum is additive and could be separate from that of endothelial cell growth supplement and heparin, inasmuch as doubling the concentrations of these two growth factors produced no further augmentation of growth in fetal calf serum–containing culture medium.

The nature of the growth stimulating factors in human pregnancy serum is unexplained. Addition of estradiol (in concentrations at or above those seen in normal pregnancy) to fetal calf serum with growth factor did not reproduce the effect. It is still possible that estrogen could produce such an effect in vivo, either metabolized to a more active form or acting as a cofactor. There are, of course, many other hormones, cytokines, and biologic response modifiers secreted in normal pregnancy that could produce such an effect alone or in combination. Experiments with antisera to these would eludicate this. Future work will address this question.

Although the decidual endothelial cells isolated with this technique are normal in apperance, in viability (as assessed by trypan blue exclusion), and in growth pattern, it is possible that the harvesting and purification procedures may have induced subtle alterations in endothelial cell function, such as cytokine production. These questions are being examined.

Because an early and central feature of preeclampsia is the abnormal interaction between placental tissue and decidual endothelium, it is clearly important to study tissue from this source. Whereas this article evaluates decidual endothelium isolated from normal pregnant subjects, we are currently applying this technique to its isolation from hypertensive women, and will compare the behavior of such cells to those of normotensive women.

We thank our obstetric colleagues for collection of biopsy material and B. Nissen and K. Jenkins for expert technical assistance.

Naoki Terakawa, MD, PhD
Hiroshi Hoshiai, MD, PhD

The publication of these proceedings is supported by an educational grant from Tokyo Tanabe Co., Ltd.

Introductory remarks

Yuji Taketani, MD, PhD, Naoki Terakawa, MD, PhD, and Hiroshi Hoshiai, MD, PhD
Tokyo, Yonago, and Osaka, Japan

Despite recent advances in the diagnosis and treatment of endometriosis, long-standing clinical problems with the disease still persist. For instance, patients with mild endometriosis may have intractable pain, whereas patients with severe disease are sometimes free of symptoms. As for infertility, the cause of infertility in women with severe disease is intuitively understandable. However, the cause of infertility in women with minimal or mild disease is obscure, thus challenging a direct cause-and-effect relationship. The natural history of the disease is still poorly understood. It is unclear whether the reappearance of endometriosis after complete surgical removal results from the remaining microscopic foci or is a consequence of newly developed lesions, because circumstances predisposing to the development of the disease, such as menstrual reflux, coelomic metaplasia, and a favorable hormonal environment, may be unaltered after treatment.

To resolve these issues, much attention should be directed to understand the etiology and histogenesis of endometriosis. At present several theories have been postulated to explain the histogenesis of endometriosis, including the implantation theory, benign metastatic theory, mechanical transplantation theory, coelomic metaplasia theory, müllerian cell rests theory, and Wölffian cell rests theory. However, no single theory can provide a proper explanation for the clinical presentation of all cases of endometriosis. Therefore this conference addressed updated concepts about the etiology and histogenesis of endometriosis; investigators who are actively working in the field of endometriosis gathered together to discuss the histogenesis and pathophysiology of endometriosis based on experimental models, histopathologic studies, and clinical findings.

The conference participants also dealt with adenomyosis. Although adenomyosis is considered a different clinical entity, a deeper insight about the etiology and histogenesis of this disease may prove useful in understanding the etiology and histogenesis of endometriosis.

Finally, we express our gratitude and appreciation to Professor Masahiko Mizuno, Chairman of the Department of Obstetrics and Gynecology, University of Tokyo, for his kind and always excellent advice and constant encouragement. We also acknowledge the educational grants from Tokyo Tanabe Co., Ltd., which made this conference and these proceedings possible.

Subserosal adenomyosis: A possible variant of pelvic endometriosis

Atsuhiko Sakamoto, MD
Tokyo, Japan

A total of 128 patients with adenomyosis were examined clinically and histologically to investigate the pathogenesis of subserosal adenomyosis. In this study 15 (11.7%) cases were classified as subserosal adenomyosis on the basis of localization of heterotopic endometrial tissues that consisted of glands and stroma. These were subclinical and incidental. The uterus was not enlarged in this type of adenomyosis. Distribution of the ectopic tissues and the patients' mean age at the time of the hysterectomy suggest that subserosal adenomyosis may develop as a variant of pelvic endometriosis. (AM J OBSTET GYNECOL 1991;165:198-201.)

Key words: Adenomyosis, subserosal adenomyosis, pathogenesis, pelvic endometriosis

Typical adenomyosis consists of scattered fragmented lesions of endometriotic tissue, including both glands and stroma, in the myometrium of the enlarged uterus.[1] The distribution and number of heterotopic endometrial foci vary from patient to patient. Some have only a few foci in the uterus, which are located mainly adjacent to the serosa. An analysis of these patients with an unusual distribution of heterotopic endometrial tissue may help elucidate the pathogenesis of adenomyosis.

In this study patients with adenomyosis were examined from a clinical and histopathologic standpoint. Special emphasis was placed on patients with an uncommon distribution of heterotopic endometrial tissue to investigate the mechanisms involved in the pathogenesis of subserosal adenomyosis.

Case and methods

Specimens from 128 patients with histologically confirmed adenomyosis were examined retrospectively. All had undergone hysterectomy at Kyoundo Hospital in Tokyo between January 1989 and July 1990. In one third of these patients, unilateral or bilateral salpingo-oophorectomy had been performed simultaneously. The ages of the patients at the time of the operation and each clinical diagnosis were taken from the clinical records.

The cut surface of the posterior wall of the uterus was examined histologically in all cases. The rest of the uterus was cut in a stepwise manner and then inspected macroscopically. When necessary additional blocks were used for histologic examination. All preparations were stained with hematoxylin and eosin. Distribution of heterotopic endometrial foci and the histologic findings in them were described. On the basis of results of histologic examination, all patients were divided into two groups: those with subserosal adenomyosis and the remainder, which were subdivided according to the topographic location of the foci in the uterus. The site of the lesion, whether corpus or cervix, was also recorded.

Results

Of the 128 cases of adenomyosis, 15 (11.7%) corresponded to the subserosal type. The foci were few in number and were located close to the subserosal surface. In some instances, a contiguous but shallow extension of the subserosal foci was found in the myometrium adjacent to the serosa. The mean age ± standard deviation of these patients was 42.9 ± 4.6 years. The mean age ± standard deviation of the patients with typical adenomyosis was 45.8 ± 7.0 years.

Both the clinical diagnosis and the postoperative histologic findings in the patients with subserosal adenomyosis are shown in Table I.

Clinically subserosal adenomyosis was not detected in any of the patients. All of them had undergone hysterectomy for diseases other than adenomyosis. Concomitant ovarian endometriosis was also found in six of the patients with subserosal adenomyosis; their ages ranged between 35 and 42 years.

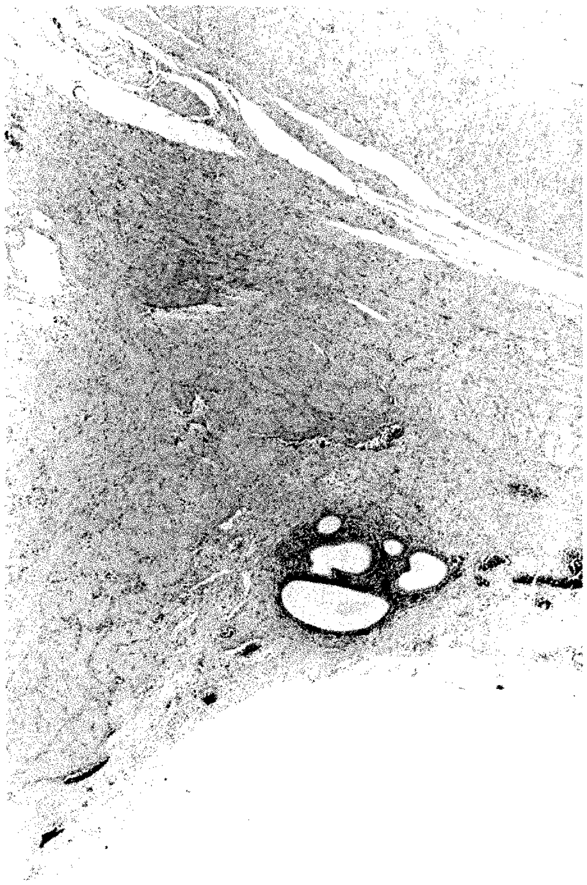

Fig. 3. Subserosal adenomyosis (case 6). Ectopic tissue was scattered in myometrium just below subserosa. Leiomyoma was also found *(upper right side)*. (Hematoxylin and eosin stain; original magnification ×40.)

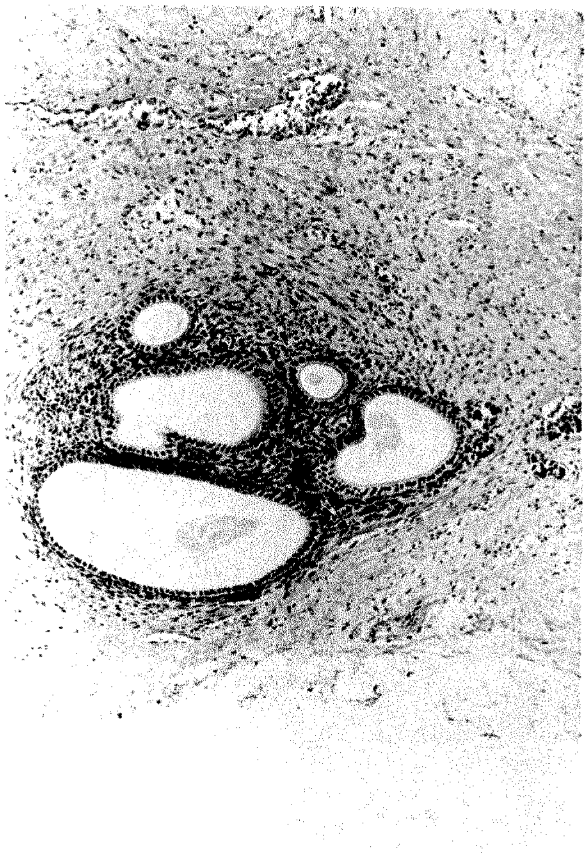

Fig. 4. High-power view of Fig. 2. Histologic findings of heterotopic tissue resemble those of basal layer of eutopic endometrium. (Hematoxylin and eosin stain; original magnification ×100.)

Regarding the location of ectopic endometriotic tissue, three were in the cervix and the remainder were in the uterine body.

The histologic findings in the ectopic endometrial tissue in subserosal adenomyosis were similar to those of the basal layer of the eutopic endometrium (Figs. 1 to 4). All foci were composed of glandular elements surrounded by stromal tissue. No hemorrhagic changes were identified in the heterotopic glands or in the stroma. There were no close correlations between the ectopic endometrial tissue and the vessels. Neither atypical nor malignant cells were found in these ectopic tissues.

Comment

The pathogenesis of adenomyosis is not well understood. In most cases of adenomyosis, ectopic endometrial tissue is found scattered within the myometrium in close correlation with the eutopic endometrium. Elongation of the endometrial basal layer into the myometrium is thought to be one of the possible mechanisms involved in the pathogenesis of this condition. However, in subserosal adenomyosis ectopic endometrial tissue is distributed in an area distant from the eutopic endometrium. It seems impossible to state that this type of disease occurs as a result of direct proliferation of the eutopic endometrium. Migration of the tissue via lymphatic channels, as postulated by Javert,[2] should also be considered as a possible mechanism. However, lymphatic permeation could not be confirmed in the cases reported here.

Previously it was suggested that subserosal adenomyosis may be a variant of pelvic endometriosis.[3-5] Some evidence, including the distribution of ectopic endometrial tissue supports this hypothesis. The mean age of the patients with subserosal adenomyosis reported in this study was 3 years less than that of the rest of the patients with adenomyosis; that is, they were about the same age at which pelvic endometriosis usually develops (the fourth decade on average).[1] It is believed that adenomyosis is not commonly associated with endometriosis, even in patients with widespread endometriosis. However, the high incidence of patients with concomitant subserosal adenomyosis and endometriosis found in this study indicates a close correlation between these two conditions.

Thus subserosal adenomyosis can be regarded as a possible variant of pelvic endometriosis, although further studies are required to confirm this theory.[6]

I thank Dr. T. Sugishita, Department of Gynecology, Kyoundo Hospital, Tokyo, for supplying the clinical data, and Ms. M. Arai, Pathology Division, Kyoundo Hospital, for technical assistance. I also thank Ms. T. Ishikawa, Department of Pathology, Faculty of Medicine, The University of Tokyo, for typing the manuscript.

Histologic study of endometriosis and examination of lymphatic drainage in and from the uterus

Minoru Ueki, MD, PhD
Takatsuki, Japan

Histologic study of endometriosis and investigation of lymphatic drainage in and out of the uterus were conducted to obtain more information on the histogenesis of endometriosis. Endometriosis is a disease originating from the normal endometrium, specifically from its basal layer. Internal endometriosis (adenomyosis) is caused mainly by direct invasion of the endometrium into the spaces located in the connective tissue of the muscle layer. Serous and ovarian types of endometriosis are frequently found together with adenomyosis. Endometrial fragments in vessels are detected in 4.5% of cases of endometriosis. Observation of serial sections proved that serous endometriosis is caused mainly by continuous or semicontinuous invasion of the tunica muscularis spaces primarily from adenomyosis lesions and partly from the endometrium. Confirmation of lymph flow into the ovary from the uterine body strongly suggests that ovarian endometriosis arises as a consequence of vascular (lymphatic) transport of endometrial fragments from adenomyosis lesions, serous endometriosis lesions, or the endometrium. (AM J OBSTET GYNECOL 1991;165:201-9.)

Key words: Histogenesis, morphology, lymphatic drainage, endometriosis

Endometriosis, which can be pathologically considered a benign proliferative lesion, is classified into internal endometriosis (adenomyosis) and external endometriosis (serous and ovarian endometriosis).

Table I. Theories concerning the histogenesis of endometriosis

Theories assuming origin in tissues other than the endometrium
Wolffian duct theory (Von Recklinghausen,[7] 1896)
Müllerian duct theory (Russell,[8] 1899)
Coelomic metaplasia theory (Iwanoff,[3] 1898; Meyer,[4] 1903)
Hormonal stimulation theory (Novak,[9] 1931)
Induction phenomenon theory (Levander and Normann,[5] 1955; Merrill,[6] 1966)
Theories assuming origin in the uterine endometrium
Direct-extension theory (Cullen,[1] 1908)
Implantation theory (Sampson,[2] 1921)
Benign metastasis theory (Halban,[10] 1924)
Uterotubal theory (Phillip and Huber,[11] 1939)
Mechanical transplantation (Greenhill,[12] 1942)

The cause of endometriosis has not yet been determined conclusively, although numerous theories concerning its histogenesis have been proposed. At present the direct-extension theory[1] for internal endometriosis and the implantation theory,[2] the coelomic metaplasia theory,[3, 4] and the induction theory[5, 6] for external endometriosis are the most favored (Table I).

The morphologic and functional characteristics of endometriotic lesions (internal and external) have already been compared with those of the endometrium (functional and basal layer) to determine the histogenesis of endometriosis (Fig. 1), and it was concluded that endometriosis was likely to originate in the endometrium because both internal and external endometriosis lesions resembled the basal layer of the endometrium.[13]

On the basis of these previous findings, in the present study adenomyosis and pelvic endometriosis were investigated from a histopathologic standpoint and lymphatic drainage in and out of the uterus was studied to determine the histogenesis of these conditions.

Material and methods

Histologic examination. To determine the relationship between adenomyosis and serous endometriosis, the incidence of lesions by site and the rate of occurrence of combinations of these lesions were determined in 278 patients with adenomyosis and pelvic endometriosis. In addition, 200 semiserial sections (5 μm thick) taken approximately 45 μm apart, which included the endometrium and the serous membrane, were prepared from 14 patients with serous endometriosis and examined after staining with hematoxylin and eosin. The incidence and patterns of endometrial fragments in the vessels were also observed in 290 patients.

Lymphatic drainage. To examine lymphatic drainage, India ink was injected into the uterine cavity after hysterectomy (13 patients). Uteri were stored for 2 days in a cold dark place and fixed in formalin. India ink was also injected directly into the uterine subserous lymphatic vessels with a 30-gauge needle immediately after hysterectomy (7 patients). Uteri were fixed in the same way. In four volunteers who gave their informed consent, India ink (0.2 to 0.3 ml) was injected into the subserous lymphatic vessels during the operation to observe the drainage in situ. To observe lymphatic drainage in the ovaries, 0.1 ml of India ink was injected under the tunica albuginea with the same needle immediately after oophorectomy (15 patients). Ovary samples were fixed in formalin after standing at room temperature for 1 hour to allow the ink to flow along the vessels. Each sample was examined after staining with hematoxylin and eosin.

Electron microscopic procedure. Uteri taken from five patients with adenomyosis were cut into small pieces and immersion fixed in 1% paraformaldehyde and 1.25% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 7.35, for 10 hours at room temperature; they were then fixed in 1% osmium tetroxide with 0.01 mol/L cacodylate buffer for 1.5 hours. Specimens were

dehydrated in graded concentrations of ethanol and embedded in Epon 812. Thin sections (60 to 80 nm thick) were double stained with uranyl acetate and lead citrate and examined with a Hitachi H 300 electron microscope.

Results

Histologic examination. The incidence of endometriosis lesions per site, determined by histologic examination in 276 patients, was 20.5% for adenomyosis alone, 1.1% for serous endometriosis alone, 5.0% for ovarian endometriosis alone, 32.7% for adenomyosis plus serous and ovarian endometriosis, 11.9% for adenomyosis plus ovarian endometriosis, 9.7% for ovarian plus serous endometriosis, and 19.1% for adenomyosis plus serous endometriosis. The incidence of serous endometriosis and adenomyosis combinations and ovarian endometriosis and adenomyosis combinations was high (65.2% and 56.1%, respectively, when adenomyosis alone was excluded from the denominator), whereas the incidences of ovarian endometriosis alone and serous endometriosis alone were low (Table II).

Results of detailed histologic examinations conducted in 14 patients with serous lesions showed a relationship with adenomyosis lesions in 78.5% of these patients (11 of 14) (Table III). Adenomyosis lesions were seen throughout the entire tunica muscularis in two patients (14.3%; Fig. 2). Although these adenomyotic lesions were present in only part of the tunica muscularis in eight patients, continuous invasion into the serous membrane from these adenomyotic lesions was seen in six of eight patients (42.9% of the total examined histologically; Fig. 3), and in two patients (14.3%) the lesions were semicontinuous. In one patient, continuous invasion of stromal cells into the serous membrane through the tunica muscularis was observed.

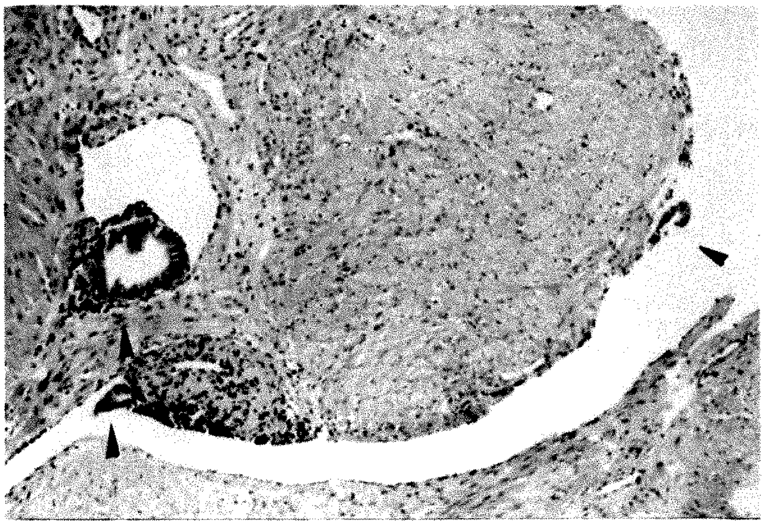

Fig. 4. Endometrial fragments in lymph vessels (attached to wall: *arrow*).

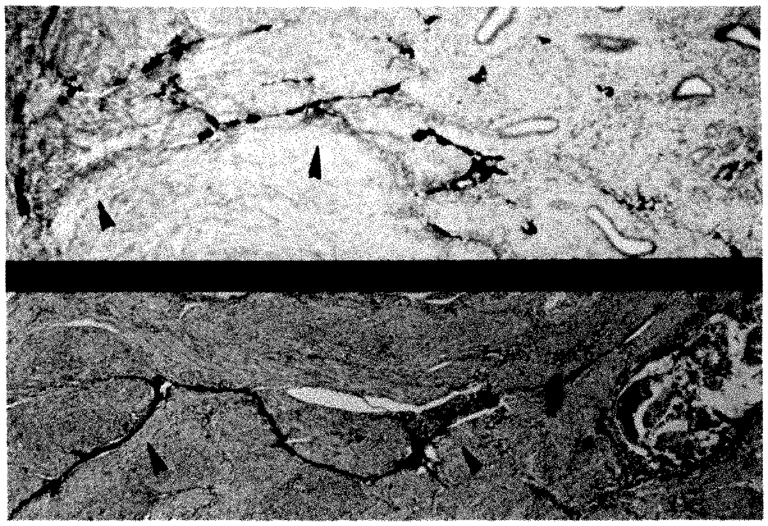

Fig. 5. Demonstration of course of flow (India ink technique). Ink flow is diffused in connective tissue space in superficial layer of endometrium, but in basal layer it is clearly seen in lymph vessel (*top*, adenomyosis case; *bottom*, endometrial cancer). *Arrows* show each lesion.

The incidence of apparent endometrial fragments in the vessels in the tunica muscularis was 4.5% (13 of 290 patients). The incidence was higher in lymphatic vessels than in blood vessels. All of these intravascular fragments consisted of glandular and stromal cells in all patients and were found attached to the vascular wall in most of them (Fig. 4).

Lymphatic drainage in the muscle layer, the subserous layer, and out of the uterus

Lymphatic drainage in the endometrial and muscle layers. The ink flowed diffusely into the connective tissue spaces of the superficial endometrial layer and spread gradually into the vessels of the middle endometrial layer. In the muscle layer the staining became more intense, and clearly delineated capillary lymphatic vessels were observed (Fig. 5). Lymph flow through the muscle layer drains toward the subserous lymph vessels. The subserous lymph in front and back of the uterus flows to bilateral sites.

Subserous lymphatic channels and drainage. These channels showed an irregular, thick, netlike distribution. The valves of the lymphatic vessels were observed. Oak leaf–like endothelial cells became visible when ink mixed with silver nitrate solution was used (Fig. 6).

The most interesting finding related to lymphatic drainage was a direct stream from the uterus to the

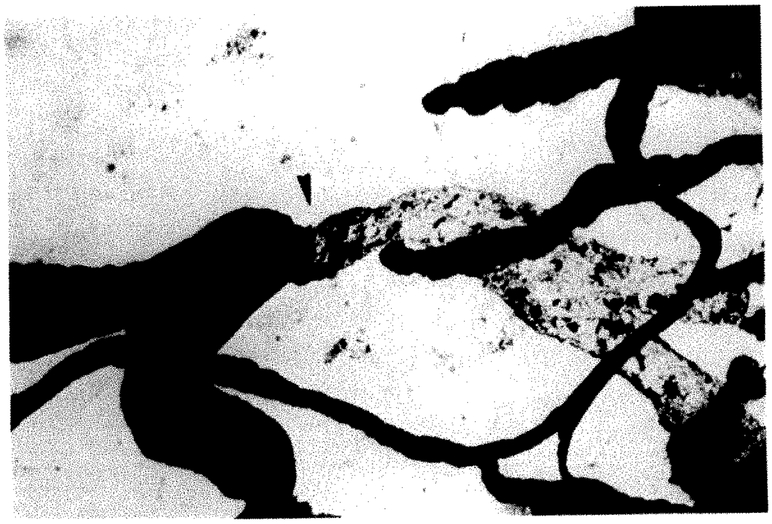

Fig. 6. Distribution of lymphatic channels and drainage in subserosa (India ink mixed with silver nitrate solution technique). *Arrow* shows site of valve.

ovaries. We confirmed the existence of this direct stream from certain areas in the uterine fundus to the ovaries by this ink method (Fig. 7).

Lymphatic drainage out of the uterus. Lymphatic drainage out of the uterus is shown in Fig. 8. The ink flowed from the uterus into the tubes, ovaries, and round ligaments. Flow from the fundus to the infundibulopelvic ligaments was identified, as well as flow from a wide area in the vicinity of the cervix reaching the cardinal ligaments. Part of the drainage to the cardinal ligaments appeared to flow back to the bladder. In the back of the uterus, lymph flowed out in the same way. At the boundary of the uterosacral ligaments, drainage appeared to be extremely complicated. On the basis of these findings and those obtained from evaluation of sites of endometrial cancer metastasis (unpublished data), routes through which lymph may flow out from the uterus were postulated (Fig. 9). The following five routes were postulated: (1) from the uterus into the internal and common iliac and aortic lymph nodes via the pelvic infundibular ligaments, (2) from the obturator, internal, and external iliac lymph nodes to the common iliac lymph nodes via the cardinal ligament, (3) to the inguinal lymph nodes via the round and umbilical ligaments, (4) directly into the ovaries, and (5) directly into the fallopian tubes.

Intrauterine lymphatics in the tunica muscularis uteri. Intrauterine lymphatics were distributed in the lamina propria mucosa, myometrium, and subserous layer and showed a variety of shapes and calibers. The lumina of lymphatic capillaries were filled with drak amorphous material in contrast to the lucent lumina of blood capillaries. Lymphatic endothelial cells were thin and flat on the luminal surface, but small projections extending into the surrounding tissue, in which hemidesmosome-like apparatuses were present, were found at various places. The basal lamina was discontinuous or absent. The most interesting finding was the presence of openings between adjacent endothelial cells in patients with

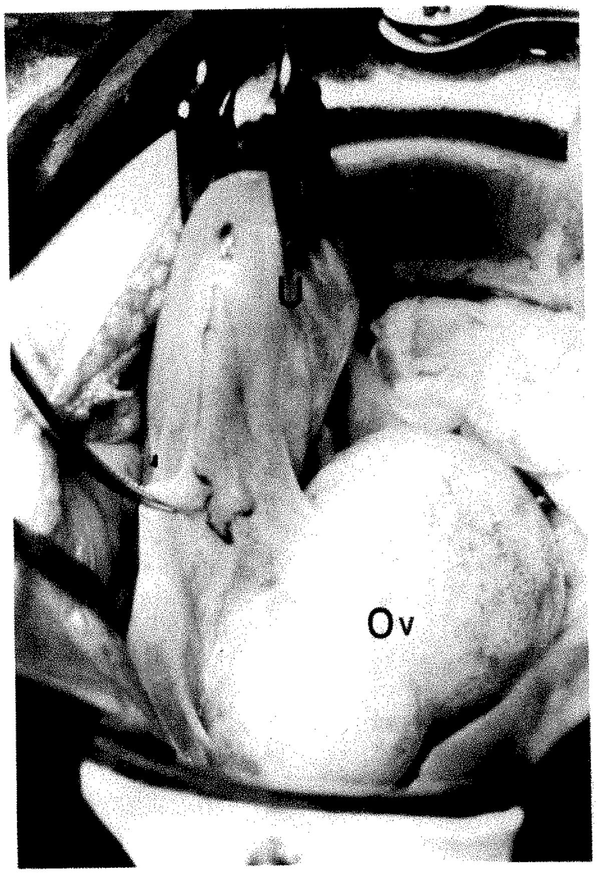

Fig. 7. Confirmation of direct lymphatic stream from uterus to ovary (India ink technique). *U*, Uterus; *Ov*, ovary.

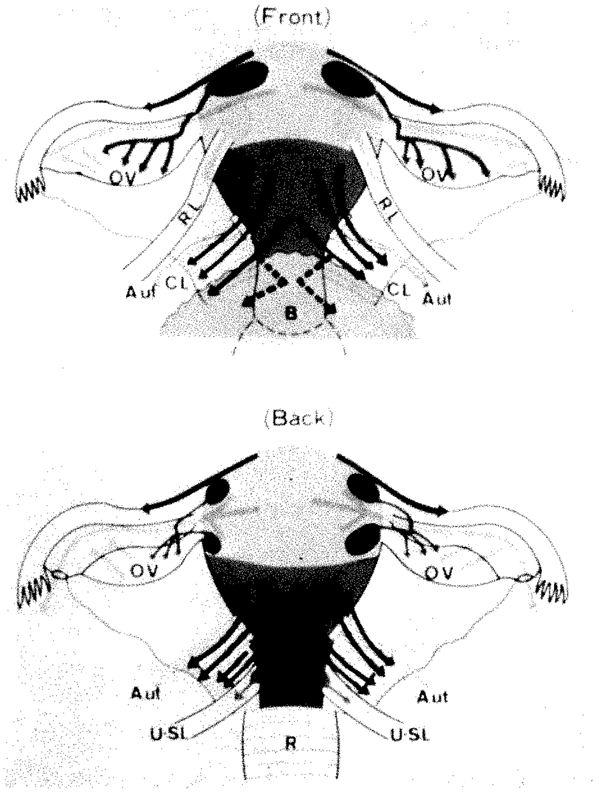

Fig. 8. Lymphatic drainage of human uterus.

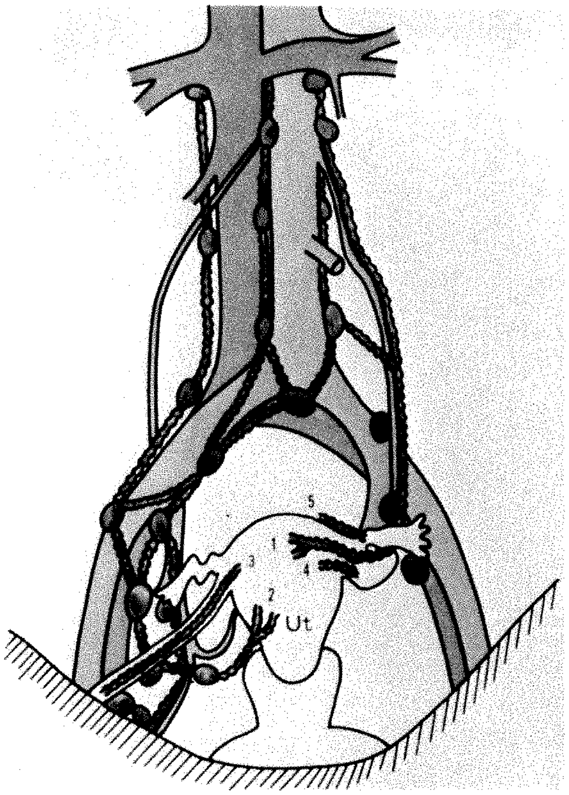

Fig. 9. Lymphatic drainage out of uterine body.

adenomyosis, inasmuch as these openings are not generally observed in lymphatic vessels under normal conditions (Fig. 10).

Lymphatic vessels in the muscle layer possessed valves in which the basal lamina was present beneath the endothelial cells (Fig. 11). The valves consisted of two endothelial cells. Lysosome-like bodies were occasionally present in the cytoplasm of these cells. The valves prevent reflux of the lymph and are involved in the transport of various substances.

Distribution of lymphatic vessels in the ovaries. India ink was found in the medullary lymphatic vessels, and ink flowed from the cortical lymphatic vessels on injection over the ovarian surface, resulting in profuse distribution. Lymphatics were abundant in the corpora lutea and were also observed in the theca folliculi externa of mature follicles and tunica albuginea.

The distribution of lymphatic vessels in the ovaries within the cortex was compared with that of the medulla; also lymphatic vessels in premenopausal and postmenopausal women were compared (Fig. 12). Lymphatic vessels in both the cortex and medulla were thick and abundant in reproductive-aged women but became narrow after menopause.

Comment

Cullen[1] reported that uterine adenomyosis occurs as a result of continuous infiltration of the endometrium into the muscle layer. Data obtained some years ago confirmed these findings.[13]

It has also been demonstrated that other factors related to the histogenesis of adenomyosis include dilatation of connective tissue spaces, increases in the number of reticular fibers, and increases in intrauterine pressure as a result of menstruation, pregnancy, delivery, abortion, and curettage.[13]

One of the most important points related to histogenesis of external endometriosis is that external lesions are morphologically and functionally very similar to the basal layer of the normal endometrium (Fig. 1). In fact, most external lesions appear to derive or metastasize from the endometrium.

The question is through which routes does metastasis occur. One route is that followed by serous endometriosis. In this instance, which is often observed in daily clinical practice, adenomyosis spreads over the muscle layer and reaches the serous membrane. This pattern, which is the result of continuous (nonvascular) invasion of endometrial fragments into the muscle layer spaces, was seen in 14.3% of 14 patients examined. Microscopically continuous (42.9%) or partially intermittent (14.3%) lesions were observed in muscle layer spaces between the adenomyosis lesions and the corresponding superficial lesions.

The incidence of serous endometriosis, which derives from adenomyosis continuously or semicontinuously,

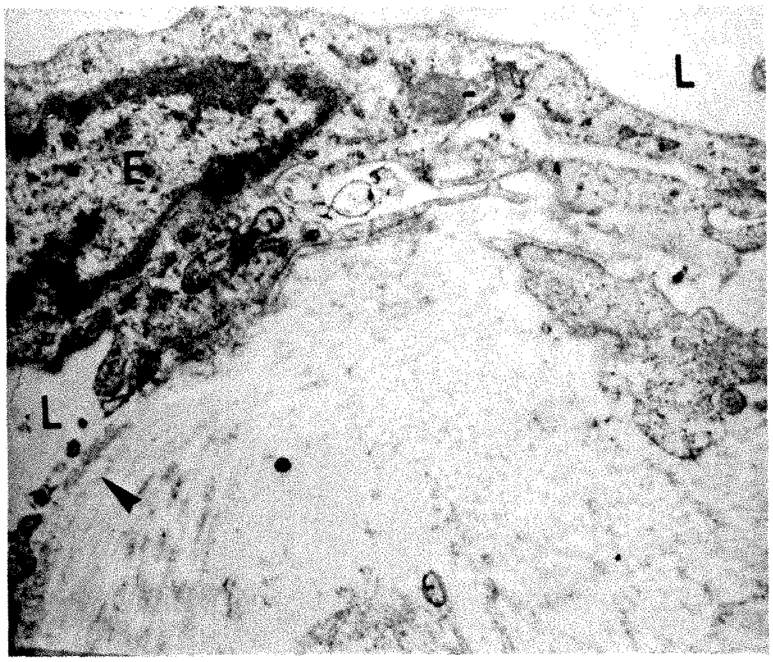

Fig. 10. Electron micrograph of lymphatic capillary. Part of lymphatic capillary shows opening *(arrow)* between adjacent endothelial cells. *L*, Lumen of lymphatic capillary; *E*, endothelial cell of lymphatic capillary.

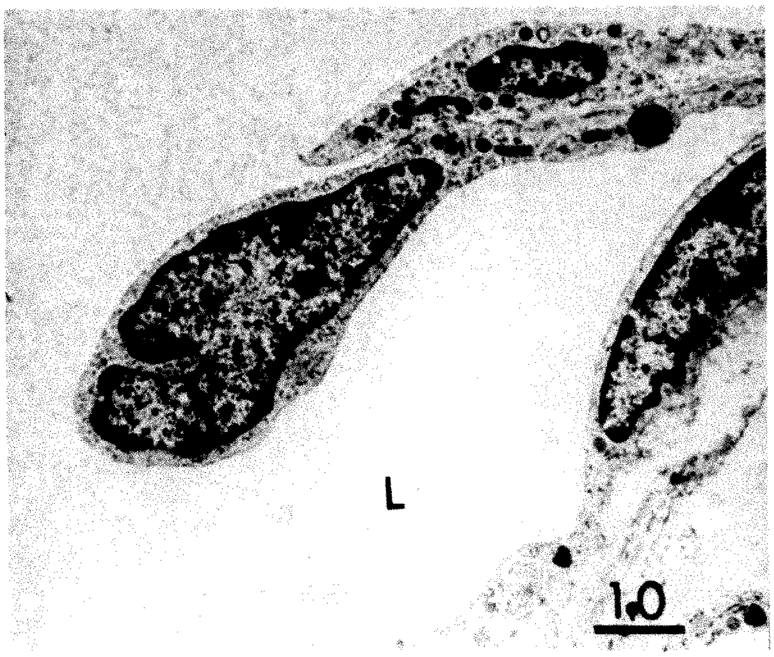

Fig. 11. Electron micrograph of lymphatic vessels showing part of valve of lymphatic vessel in muscle layer of uterus. Valve consists of two endothelial cells. *L*, Lumen of lymphatic vessel.

is thought to be quite high if that derived from the endometrium is also included.

The transvascular implantation theory advocated by Halban[10] is another example. In the present study endometrial fragments were detected in the lymphatic vessels of the muscle layer in 4.5% of patients. Endometrial fragments were found floating in the lymphatic vessels in only a few patients. In most instances part or approximately one half of the endometrial fragment surface was in contact with the wall of lymphatic vessels,

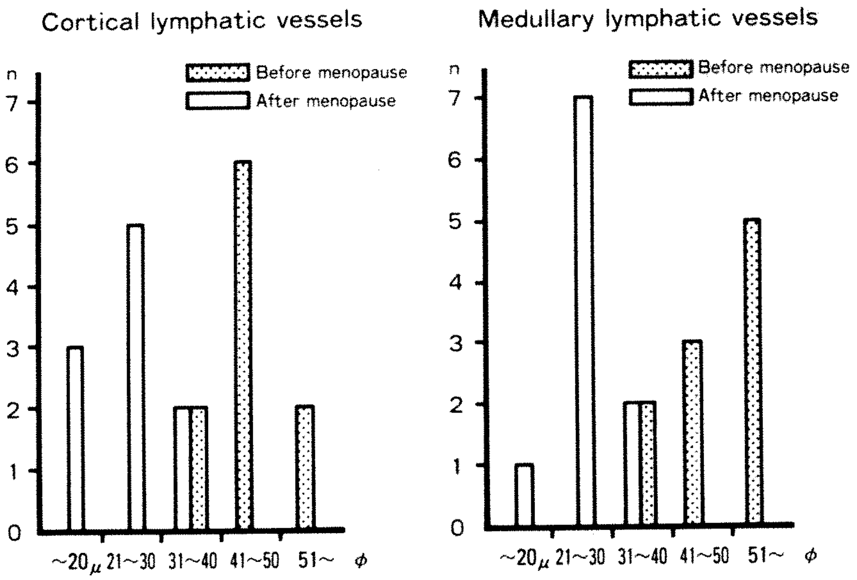

Fig. 12. Distribution of lymphatic vessels in ovaries.

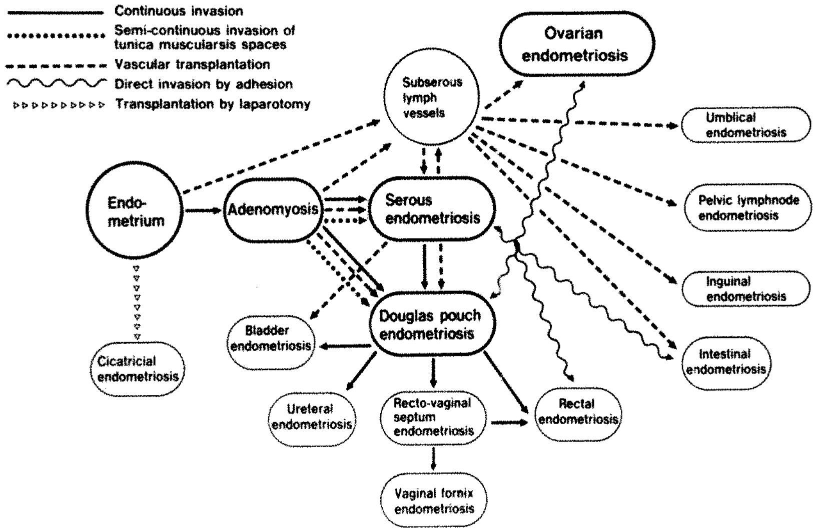

Fig. 13. Diagram showing histogenesis of endometriosis.

giving the impression that these fragments moved forward by changing their shape on the wall to which they closely adhered. This process needs to be studied further to obtain more insight into how an endometrial fragment or a cancer cell metastasis occurs.

As shown in Fig. 10, endothelial cells of capillary lymphatic vessels are opened by changes in tissue pressure. Endometrial fragments and cancer cells may enter the lymphatic vessels from these openings.

Only a few studies have been conducted on lymphatic vessels and capillary lymphatic drainage in the uterus and their microstructure.[14] This study on lymphatic drainage conducted with India ink showed that the ink was absorbed into the endometrium from the intrauterine cavity by entering vessels that seemed to be capillary lymphatic vessels from connective tissue spaces in the endometrial layer. The ink flow gradually became thicker and entered the lymphatic vessels in the muscle layer and then proceeded into the network of abundant large lymphatic vessels under the serous membrane. This flow seemed to have five routes: pelvic infundibular ligament, lymphatic vessels in the cardinal ligament, ovaries, fallopian tubes, and round ligament. The first two would be the main routes. It is interesting that these routes are consistent with the sites and incidence of metastasis of endometrial cancers.

With regard to the relationship between lymph flow into the ovaries and serous endometriosis, the lymph flow into the ovaries may occur readily through part of the uterine body. The influx may occur from vessels at the ovarian hilus and the adjacent cortical areas. Ovarian and serous types of endometriosis were very closely related not only to each other but also to adenomyosis; serous endometriosis and adenomyosis seem to be involved in the development of ovarian endometriotic lesions.[15] Transvascular implantation seems to be the most likely mechanism involved in the pathogenesis of ovarian lesions.

In conclusion, on the basis of the preceding findings endometriosis would seem to be mainly the result of continuous or semicontinuous invasion and vascular transplantation of the endometrium (Fig. 13). Concerning ovarian endometriosis, other mechanisms besides endometrial transplantation might be involved in its pathogenesis; however, they were not referred to in this article.

The following factors seem to be of critical importance in elucidating the histogenesis of endometriosis in the future: (1) to further clarify the histopathologic definition of endometriotic lesions; (2) to determine whether endometriotic lesions derive only from the endometrium or from other places as well; (3) to remember that endometrial tissues (fragments) are able to either continuously or noncontinuously infiltrate nearby tissues; (4) to take note that flow of lymph and other body fluids in and out of the uterus cannot be neglected as possible pathways; (5) to compare the mechanisms of invasion of adenomyosis and endometrial cancer; and (6) to review the incidence of conditions that match the definition of pulmonary, subcutaneous, pelvic lymph node, and ovarian endometriosis.

I thank Professor O. Sugimoto, Dr. T. Sano, and Dr. K. Otsuki for their cooperation.

Peritoneal endometriosis: Endometrial tissue implantation as its primary etiologic mechanism

Tadayuki Ishimaru, MD, PhD, and Hideaki Masuzaki, MD, PhD
Nagasaki, Japan

The mechanisms involved in primary implantation of pelvic endometriosis were investigated in women undergoing laparoscopy as part of an infertility evaluation. Among the women with a diagnosis of endometriosis, those with no observed lesions in the ovaries and no adhesions in the pelvic cavity were classified as being in stage I. These women were further subdivided into two groups: the stage Ia group in which implants were found in one area (25 women) and the stage Ib group in which implants were found in two or more areas (29 women). In both groups the most frequent site was the uterosacral ligaments followed by the posterior uterine serosa, the posterior cul-de-sac, and the posterior broad ligaments in that order. Regardless of the position of the uterus, endometriosis was found significantly more frequently in the posterior compartment. The finding that the most frequent implants on the uterosacral ligaments were near the tubal ostium and, in the stage Ia group, the absence of implants on the anterior uterine serosa but a 33% frequency on the posterior uterine serosa, which is more frequently exposed to menstrual blood, suggest that implantation of endometriosis is the result of retrograde menstruation. However, the possibility that metaplasia of the serosal epithelium is stimulated by menstrual blood cannot be ruled out, inasmuch as the process of implantation in the peritoneum has not yet been proved. (AM J OBSTET GYNECOL 1991;165:210-4.)

Key words: Etiology, endometriosis, laparoscopy, retrograde menstruation

The location of endometrial implants is considered important in the study of the mechanisms of implantation of peritoneal endometriosis in the pelvic cavity. This article examines the validity of Sampson's[1] regurgitation theory by studying the distribution of the disease in patients in the early stage of peritoneal endometriosis in the pelvic cavity.

Material and methods

Of the patients visiting our infertility clinic in whom endometriosis was diagnosed by laparoscopy, those with implants only on the serosa in the pelvic cavity and with no adhesions or ovarian endometriosis were defined as being in the early stage of endometriosis (stage I). These patients were divided into two groups: the stage Ia group in which lesions were found in only one area (25 patients), and the stage Ib group in which lesions were found in two or more areas (29 patients). Biopsy samples were obtained from patients with typical findings such as blueberry spots and blood blebs. Furthermore, yellow-brown peritoneal patches and red flame-like lesions similar to those described by Jansen and Russell[2] were also investigated histopathologically.

Table I. Location of endometriotic lesions

Location	*Ia (%)*	*Ib (%)*	*All of stage I (%)*
Round ligament	0/25 (0)	5/29 (17)	5/54 (9)
Anterior uterine serosa	0/25 (0)	3/29 (10)	3/54 (6)
Posterior uterine serosa	7/25 (28)	20/29 (69)	27/54 (50)
Tube	0/25 (0)	5/29 (17)	5/54 (9)
Posterior cul-de-sac	5/25 (20)	11/29 (38)	16/54 (30)
Posterior broad ligament	3/25 (12)	10/29 (34)	13/54 (24)
Anterior broad ligament	0/25 (0)	0/29 (0)	0/54 (0)
Uterosacral ligament	10/25 (40)	20/29 (69)	30/54 (56)

Experimental endometriosis was induced as follows: A portion of the uterine serosa of a 10-week-old Sprague-Dawley rat (240 to 260 gm), was cut open and several 5 × 5 × 1 mm pieces of tissue were obtained, which included endometrium. The pieces of tissue were sutured onto two sites—the mesenterium and the retinaculum uterus—with a 4.0 nylon thread with the endometrium side toward the abdominal cavity. Three weeks after transplantation, laparotomy was performed to examine the transplanted tissue macroscopically and histopathologically.

Results

As shown in Table I, in the stage Ia group the most frequent site of endometriosis was the uterosacral lig-

aments (49%), followed by the posterior uterine serosa (28%), the posterior cul-de-sac (20%), and the posterior broad ligaments (12%). In the stage Ib group both the uterosacral ligaments and the posterior uterine serosa were equally common sites (both 69%), and the posterior cul-de-sac was also a common site for endometriosis (38%).

When our study population was considered as a whole, the most common site of endometriotic lesions was the uterosacral ligaments (56%), followed by the posterior uterine serosa (50%), the posterior cul-de-sac (30%), and the posterior broad ligaments (24%). Implants were also found on the round ligaments (9%), the fallopian tubes (9%), and the anterior uterine serosa (6%), but they were not found on the anterior broad ligament. The preceding results were reexamined by dividing the pelvic cavity into two compartments. The anterior compartment consisted of the anterior cul-de-sac, the anterior broad ligaments, and the anterior uterine serosa. The posterior compartment included the posterior cul-de-sac, the posterior broad ligaments, the posterior uterine serosa, the uterosacral ligaments, and the sigmoid colon. In the stage Ia group implants were found only in the posterior compartment, whereas in the stage Ib group 76.3% of the implants were found in the posterior compartment and 23.7% in the anterior compartment (Table II). In the 38 (of 54) patients with primary infertility in both stage Ia and stage Ib groups, the most frequent site was the uterosacral ligament, followed by the posterior uterine serosa, and the posterior cul-de-sac.

With regard to the relationship between the position of the uterus and the location of the implants, 88.6% of patients with anterior uteri (38 patients) were found to have implants in the posterior compartment and 11.4% of them had implants in the anterior compartment. Among patients with posterior uteri (16 patients), 83.3% had implants in the posterior compartment and 16.7% had implants in the anterior compartment. In both positions implants were found much more frequently in the posterior compartment. There were no patients with implants in the anterior compartment only.

The results of the experiments in rats were as follows: On the sutured part, a unilocular cyst filled with transparent fluid was observed (Fig. 1). On examination of the tissue, a glandular structure was observed on the inner surface of the cyst, and the intraglandular space was filled with fluid and the presence of active glands noted. The glandular structure was covered with

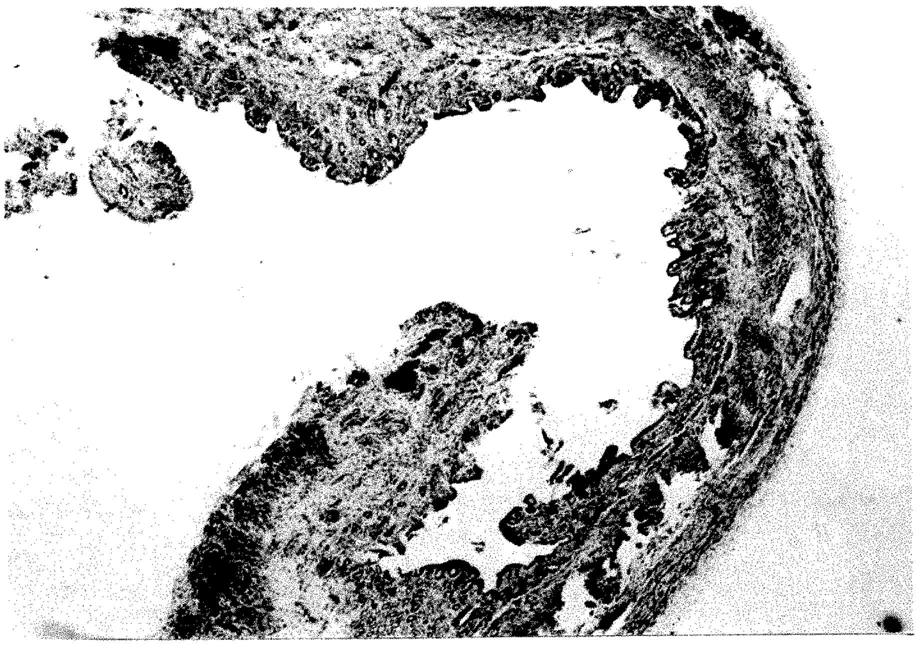

Fig. 2. Glandular structure covered by simple epithelium and connective tissue.

simple epithelium and connective tissue—the intact serosa (Fig. 2). Many blood vessels were observed around the glandular structure.

Comment

We found that in patients with pelvic endometriosis affecting the serosa only and with no adhesions, endometriotic implants were located much more frequently in the posterior compartment compared with the anterior compartment. Particularly in patients with lesions in only one area (stage Ia), implants were found in the posterior compartment only. Jenkins et al.,[3] who conducted similar investigations, reported that in those patients with a severely anteflexed uterus, implants were found in the anterior compartment only. In our previous study in which lateral-view hysterosalpingograms were used, we found that in patients with a retroflexed uterus, most of the contrast medium 24 hours after administration had accumulated in the posterior compartment (unpublished observations). In patients with an anteflexed uterus, the contrast medium diffused into both compartments, but the amount was larger in the posterior compartment. This indicates that regardless of the position of the uterus, except in patients with a severely anteflexed uterus, menstrual blood would accumulate in the posterior compartment centering around the posterior cul-de-sac. In other words, the finding that in the earliest stages of the disease endometriotic implants are seen more frequently in the posterior compartment means that implantation is likely to occur where menstrual blood has accumulated. Considering the location of the tubal ostium, which is situated close to the point of insertion of the uterosacral ligament, it is quite interesting to note that the most frequent site of implantation in incipient endometriosis is at the uterosacral ligaments. The finding that in the stage Ia group the implantation frequency in the anterior uterine serosa was 0% compared with 33% in the posterior uterine serosa, which is more frequently immersed in menstrual blood, seems to support Sampson's implantation theory. Theoretically, suitable sites for transplantation occurring as a result of retrograde menstruation are: (1) sites immersed in menstrual blood, (2) sites likely to be influenced by gravity, and (3) fixed organs. Actual implant locations as reported here corresponded to these possible sites.

However, several problems have been pointed out in relation to Sampson's theory. First, can endometrial particles go through the uterine tubes? Second, can endometrium that is cast off at the time of menstruation survive and have the ability to grow elsewhere within the pelvic cavity? Third, serosal lesions are located at a certain depth under the serosa and are always covered with healthy serosa. This suggests a transvascular migration mechanism, which supports the theory of lymphatic and vascular metastasis.

In response to the first question, the presence of endometrial fragments in the isthmic portion of the tubal lumen has already been demonstrated.[4] Endometrial cells and endometrial fragments are often found in hemorrhagic ascites collected during laparoscopy conducted at the time of the menstrual period

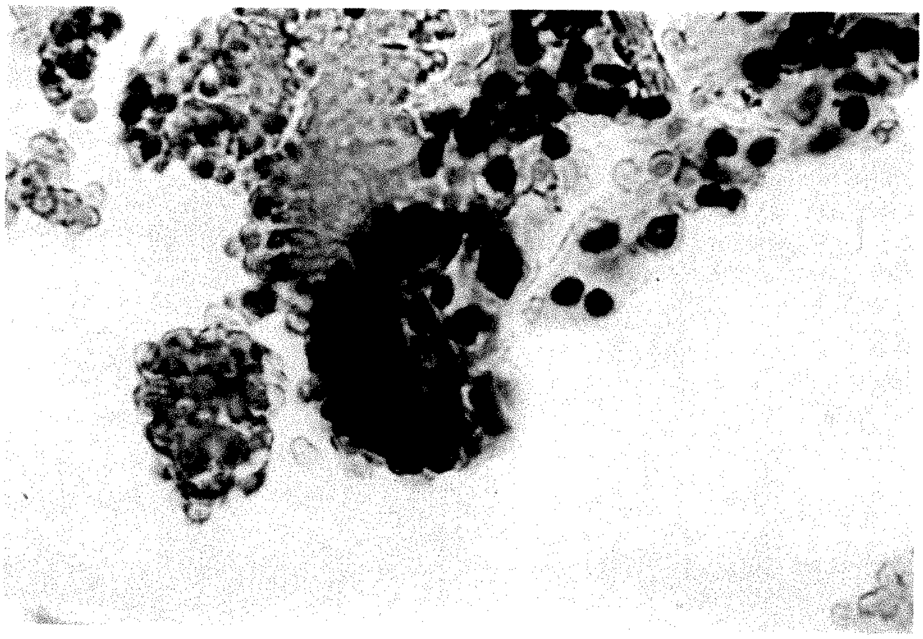

Fig. 3. Endometrial fragments in abdominal fluid obtained on fourth day of menstruation.

(Fig. 3). These facts prove that the endometrial fragments usually pass through the fallopian tubes and are discharged into the abdominal cavity.

In response to the second question, in vitro cultivation and transplantation experiments of endometrium at the time of menstruation have proved that cast-off endometrium has the ability to grow at ectopic locations.[5] In this regard results of the experiment by Te Linde and Scott[4] are very interesting. Te Linde and Scott[4] performed laparotomy on *Macacus rhesus* monkeys. They made a cut at the cervix, or in some instances at the vagina, then turned the uterus 180 degrees so that the opening of the cervix was toward the head, and then fixed it. This way the menstrual blood flowed around the sigmoid colon and into the abdominal cavity. After a certain period of time, they performed a second laparotomy and reported the presence of endometrial implants in the sigmoid colon and the cervix. On the other hand, Ridley and Edward[6] injected endometrial fragments found in human menstrual blood into the abdominal fascia above the symphysis pubis at the midline and found endometriosis at the injection site 175 days later.

Thus the viability and transplantability of endometrial fragments in the menstrual blood have been well documented.

In response to the third question, the discussion is based on the results of our experiments in rats. The endometrium transplanted on the mesenterium or the retinaculum uterus was covered by the intact serosa. The results of this experiment demonstrate that serosal lesions covered by healthy serosa do not necessarily arise from vascular metastasis, but they can also develop after implantation of endometrial fragments on the surface of the serosa. Rock et al.[7] conducted a histologic study with the use of 50 fallopian tubes cut off at the proximal segment from 25 patients who desired a reversal operation 1 to 4 years after tubal sterilization. They reported the presence of endometriosis at the tip of the proximal segment of the ligated tube. Some patients also had fistulas at the tip and had endometriotic implants at those fistulas. In these 25 patients no endometrial implants were observed on the serosa in the pelvic cavity or the ovaries. Two other facts support Sampson's theory. First, endometrial implants are frequently found at sites such as the fimbria, where menstrual blood regurgitates into the abdominal cavity. Here perifimbrial adhesions occur frequently, and their morphologic structure allows debris from menstrual blood to adhere easily. Second, in many patients with endometriosis tubal patency is preserved. However, we have neither found nor read any evidence proving endometrial transplantation to the serosal surface of the pelvic cavity. On the other hand, endometrial implants in the pelvic cavity of patients with primary amenorrhea or endometrial hypoplasia[8] have been reported, and some of these implants can only be explained by the coelomic metaplasia theory. Furthermore, there is a mesenchyme with multipotential properties just below the mesothelium that originates from the coelomic epithelium. The presence of this tissue satisfies the concept of the secondary müllerian system theory.[9] The peritoneum has the potentiality to be transformed into tissue that bears strong similarities to the müllerian duct, and it is possible that metaplasia at the serosal epithelium occurs when it is stimulated by menstrual blood and it develops further into endometriotic lesions. Notwithstanding these findings, which speak against Sampson's theory, the results presented here, as well as those of other reports in the literature, constitute strong evidence in favor of this theory. Implantation of endometrial tissue that reaches the pelvic cavity as a result of retrograde menstruation would be the primary etiologic mechanism of pelvic endometriosis.

A reappraisal of the coelomic metaplasia theory by reviewing endometriosis occurring in unusual sites and instances

Hiroshi Suginami, MD, D Med Sci
Ehime, Japan

Endometriosis occurring in unusual sites and instances was reviewed for the purpose of exploring the pathogenesis of the disease. Endometriosis is frequently observed in the pelves of menstruating women. It occurs in teenagers even before menarche, in women who have never menstruated, and in postmenopausal women. It affects not only the pelvic organs but also the right-sided thoracic organs and rarely the extremities. It occurs in men who are castrated and treated with estrogen. The affected sites in both common and uncommon endometriosis include cells arising from the coelomic membrane and sites exposed to metaplasia-inducing substances such as estrogen and unknown factors liberated from the degenerating endometrium. This appears to strengthen the coelomic metaplasia theory, although additional basic and experimental data must still be accumulated to confirm this theory. (AM J OBSTET GYNECOL 1991;165:214-8.)

Key words: Endometriosis, pathogenesis, coelomic metaplasia

Endometriosis is an enigmatic disease that affects women of reproductive age. It causes pelvic pain, dysmenorrhea, dyspareunia, and infertility. Its prevalence is reported to be 4.5% to 33.3% in women admitted for evaluation and treatment of infertility, 4.5% to 21.2% in those admitted for pelvic pain, and 0% to 7.1% in those admitted for pelvic masses.[1] Since it is not rare and it causes rather severe clinical manifestations, endometriosis has been studied extensively, and many theories have been proposed to explain the pathogenesis of endometriosis. Two of these theories are currently thought to be the most plausible: the implantation theory and the coelomic metaplasia theory.

The implantation theory was presented by Sampson.[2]

This theory postulates that viable endometrial tissue is regurgitated at the time of menses via the oviducts and is implanted on the peritoneal surface and the pelvic organs.

The coelomic metaplasia theory was proposed and supported by Iwanoff[3] and Meyer.[4] The theory states that endometriosis develops from metaplasia of cells lining the pelvic peritoneum. The theory was strengthened by the results of Gruenwald's[5] embryologic studies.

Endometriosis mainly affects pelvic organs.[6] It is also known to occur in remote regions such as the lung, pleura, diaphragm, intestine, gallbladder, kidney, ureter, and umbilicus and in the extremities; it can even occur in men, although such endometriosis is rare. In the present article such unusual cases of endometriosis will be reviewed, and the plausibility of the two major theories will be discussed.

Emdometriosis occurring in adolescent girls

There are numerous case reports of endometriosis occurring in adolescent girls.[7-25] It may occur in girls as young as 10 and 12 years of age.[9, 11, 21] Endometriosis occurring shortly after menarche is found frequently but not exclusively in young girls with müllerian anomalies causing outflow tract obstruction. Schifrin et al.[15] reported 15 cases of adolescent endometriosis verified at operation, six of which had müllerian anomalies and nine of which did not. According to their data, time intervals between menarche and surgery in the two groups were calculated to be 3.0 ± 1.9 and 6.6 ± 1.8 years (mean ± standard deviation), respectively, the former being significantly shorter than the latter ($p < 0.05$). Endometriosis is observed not only in girls with müllerian anomalies but also in those with normal pelvic anatomy. Goldstein et al.[21] diagnosed endometriosis by laparoscopy in 74 (52.9%) of 140 adolescent girls with intolerable pelvic pain of unknown origin, 66 (89.2%) of whom had normal pelvic anatomy. Bullock et al.[16] diagnosed endometriosis in 9 (50%) of 18 adolescent girls with incapacitating dysmenorrhea, but pelvic anatomy was not described.

Outflow tract obstruction enhances transtubal regurgitation of menstrual flow, which contains endometrial debris and other known and unknown factors. The fact that endometriosis occurs rather frequently in girls with outflow tract obstruction and if it occurs it becomes clinically evident earlier in these girls than in those with normal pelvic anatomy may be important and suggestive of the pathogenesis of endometriosis. This is sometimes regarded as evidence that strengthens the implantation theory.

However, the implantation theory has been challenged. Clark[9] reported a 16-year-old girl who underwent laparotomy because of uncontrollable dysmenorrhea and in whom endometriosis was found to be developing in the left cornu of a bicornuate uterus. The girl had had pain in the lower quadrant of a monthly cyclic nature and of 3 to 4 days' duration since 8 months before menarche. Menarche at 12 years of age was accompanied by the same pain noted each of the previous months, but the pain was slightly more intense. Thereafter the pain became more severe with each menses and medical treatment was ineffective, which compelled her to undergo laparotomy. In this patient the periodic pain starting before menarche suggests that endometriosis had already developed before the endometrium started to respond to ovarian steroids. El-Mahgoub and Yaseen[26] reported endometriosis in a 26-year-old woman who had never menstruated even after estrogen-progestin supplementation. Whitehouse[27] and Seitz[28] described the occurrence of endometriosis in similar cases. None of these was associated with outflow tract obstruction. Development of endometriosis in these instances cannot be explained by the implantation theory.

Endometriosis occurring in the diaphragm, the pleura, and the lungs

Major symptoms of pleural/diaphragmatic endometriosis are catamenial pneumothorax, hemothorax, and chest pain. Slasky et al.[29] reviewed 63 cases of catamenial pneumothorax and noted the following constant clinical features: (1) Its temporal relation to menstruation. It occurs within 48 to 72 hours of the onset of menstrual flow and does not occur at other times in the menstrual cycle. (2) The right-sided predominance of the occurrence. The incidence of right-sided pneumothorax is approximately 90% in catamenial pneumothorax, whereas it is 57% in idiopathic spontaneous pneumothorax. (3) Its age distribution. It occurs in the third and fourth decades of life. Idiopathic spontaneous pneumothorax shows a peak incidence at a younger age. (4) The recurrent nature of the condition. Each episode of pneumothorax is associated with menses, although not all of menses are associated with pneumothorax. (5) Its relation to ovulation. Most reported instances were in parous women and none occurred during pregnancy. Suppression of ovulation may relieve the symptoms.

Twelve cases of histologically proved parenchymal pulmonary endometriosis have appeared in the literature, including one reported by us.[30-41] Clinical manifestations have included catamenial hemoptysis (6/12 cases), chest oppression (2/12), x-ray findings (3/12), and catamenial pneumothorax (1/12). It is noteworthy that 10 (83.3%) of the 12 patients had endometriotic foci in the right lung.

Hobbs and Bortnick[42] performed an experimental study to investigate the pathogenesis of pulmonary endometriosis. They excised endometrium from rabbits and injected the tissue into the ear vein of the same animals. Pulmonary endometriosis developed in 19 (79.1%) of the 24 rabbits treated. From this they proposed that hematogenous metastasis of the endometrium is the pathogenic mechanism of pulmonary endometriosis.

The right-sided predominance of both pleural/diaphragmatic and pulmonary endometriosis, however, could not be explained by the theory of hematogenous metastasis. Allen[43] stated that particles less than 22.5 μm enter into diaphragmatic lacunas in the peritoneal lining of the diaphragm. When this occurs regurgitated endometrial glands and stromal cells have a limited chance of passing through this physiologic sieve. Rosenshein et al.[44] documented that when ^{32}P is injected intraperitoneally, nearly all of the injected material passes through the right diaphragm or liver capsule. Merrill[45] demonstrated that degenerating but not intact endometrium liberates a metaplasia-inducing substance that passes through a Millipore filter. It is well known that peritoneal fluid circulates in a clockwise direction, running down the left peritoneal gutter, across the pelvic floor, up the right peritoneal gutter, and to the right diaphragm. This current transports small particles such as estrogen and a metaplasia-inducing substance to the right diaphragm and subsequently to the right pleural cavity. Since the pleura arises from the coelomic epithelium, the same as the peritoneum and the müllerian ducts, it might have the potential to develop into endometriosis under stimulation by metaplasia-inducing substances. In this way the occurrence of pleural/diaphragmatic and parenchymal pulmonary endometriosis and its right-sided predominance could be better explained by the coelomic metaplasia theory.

It is debatable, however, whether regurgitated endometrial glands and stromal cells pass through the diaphragm and are implanted on the pleura, since there may be cribriform fenestrations in the diaphragm that are more predominant in the right than in the left diaphragmatic leaf. Foster et al.[46] reviewed 41 cases of surgically treated catamenial pneumothorax. Pleural/diaphragmatic endometriosis was diagnosed in 32 cases, 27 (84.4%) of which were without diaphragmatic fenestrations and only five (15.6%) of which had fenestrations. Slasky et al.[29] reviewed 48 cases of catamenial pneumothorax in patients undergoing thoracotomy. They found diaphragmatic defects in 16 (33.3%), pleural/diaphragmatic endometriosis in 17 (35.4%), and both diaphragmatic defects and endometriosis in nine (18.87%). The implantation theory could be applied to explain the pathogenesis of thoracic endometriosis if diaphragmatic defects were found in the majority of cases. However, since this was not the case, it is difficult to accept the implantation theory as far as the pathogenesis of thoracic endometriosis is concerned.

Endometriosis occurring in the extremities

Although it is extremely rare, it is well known that endometriosis occurs in the extremities.[47-52] In the reported cases local pain occurred or became worse at menses. In all instances the tissues excised were histologically characteristic of endometriosis.

Gruenwald[5] introduced the coelomic metaplasia theory to explain the occurrence of endometriosis in the extremities. The mesenchymal limb buds develop adjacent to the coelomic epithelium during early embryonic development when the coelomic epithelium is still differentiating into various cell types. There is a good chance for the coelomic membrane–related cells to be misintegrated into the limb buds. The misintegrated coelomic cells possess the potential to develop into endometriosis under stimulation by metaplasia-induced substances such as ovarian steroids. There is no other reasonable and plausible explanation for the occurrence of this rare type of endometriosis.

Endometriosis occurring in men

Four cases of endometriosis occurring in men have been reported, three in the urinary bladder and one in the abdominal wall.[53-56] All were in older men with carcinoma of the prostate treated with local resection, orchiectomy, and long-term, high-dose estrogen therapy. Recurrent episodes of hematuria were noted in all three cases of endometriosis of the bladder, two of which showed polypoid lesions on cystoscopy and one with an ulceration. The histologic findings of the resected specimens were characteristic of endometriosis. Symptoms subsided only when estrogen therapy was discontinued. It is obvious that the endometriosis in these cases cannot be explained by the implantation theory. It is thought that these cases provide evidence supporting the coelomic metaplasia theory.

Conclusion

With regard to the occurrence of endometriosis in unusual sites and instances, the coelomic metaplasia theory provides the most reasonable explanation. The coelomic metaplasia theory could also explain the occurrence of endometriosis in the pelves of adult women. It is not justifiable to discriminate these two types of endometriosis in the discussion of its pathogenesis. Wherever it occurs the affected sites include cells arising from the coelomic membrane that are exposed to metaplasia-inducing substances such as estrogen and a factor liberated from degenerating endometrium (Merrill factor).[15] It is well recognized that the peritoneal fluid concentration of estradiol is as high as 300 to 1000 pg/ml during the late follicular and luteal phases of the ovulatory cycle. Transtubal regurgitation of menstrual blood is a common phenomenon. Menstrual blood is abundant in endometrial debris and therefore so is the Merrill factor. It is natural to assume that female pelvic organs are constantly exposed to such metaplasia-inducing substances, since human beings assume an upright position. This appears to be the reason why endometriosis mainly affects pelvic organs of women of reproductive age.

Because of a lack of supporting basic evidence, the coelomic metaplasia theory is sometimes criticized as follows: (1) Why does endometriosis occur exclusively in women? There are only four reported cases of endometriosis in men. Isn't male endometriosis attributable to estrogen stimulation of the prostatic utricle, a müllerian remnant in men? (2) Why does endometriosis mainly affect the pelvic organs? It should occur in any site where cells arising from the coelomic membrane are present. (3) Why does endometriosis occur almost exclusively in women of reproductive age? The frequency of epithelial metaplasia elsewhere increases with age. (4) Why does endometriosis almost inevitably occur in women with functioning endometrium?

However, these criticisms can be turned around: (1) Endometriosis does occur in men if their estrogen levels are overwhelmingly superior to negligible androgen levels.[53-56] (2) Endometriosis indeed occurs wherever coelomic cells are present. (3) Endometriosis occurs in prepubertal girls[9] and also in postmenopausal women.[57-61] Endometriosis occurs even in women who have never menstruated.[26-28]

Thus the coelomic metaplasia theory favorably explains the origin of endometriosis regardless of the sites, conditions, or instances of its occurrence. It is necessary, however, to accumulate more basic and experimental data to confirm the coelomic metaplasia theory.

Secondary müllerian system and endometriosis

Shingo Fujii, MD
Kyoto, Japan

The pathogenesis of endometriosis is controversial. The two principal histogenetic theories are (1) metastases of endometrial tissues to an ectopic location (metastatic theory) and (2) metaplastic development of endometrial tissue at the ectopic site (metaplastic theory). Studies on the development of the coelomic cavity and the müllerian duct, as well as expression of CA 125 during the fetal period and in the adult, strongly suggest that coelomic epithelium–related tissues and müllerian-derived epithelia of the adult have a shared embryologic ancestry. Many manifestations of müllerian-directed metaplasia suggest that tissues derived from the coelomic epithelium and its accomanying mesenchymal cells, referred to as the "secondary müllerian system," have the potentiality to differentiate into müllerian-directed epithelium and stroma. This metaplastic potentiality of the secondary müllerian system constitutes a basic concept in the pathogenesis of endometriosis. (AM J OBSTET GYNECOL1991;165:219-25.)

Key words: Secondary müllerian system, müllerian-directed metaplasia, CA 125, endometriosis

Endometriosis is one of the most commonly encountered diseases in gynecology and infertility clinics. However, this disease is an enigma because both its cause and pathophysiology remain poorly understood. It is known that ectopic endometrial tissue is sensitive to the estrogen produced during the menstrual cycle and that the disease regresses after menopause.

Endometriosis is defined as the presence of endometrioid epithelium and stroma in an ectopic site excluding the myometrium; ectopic endometrium within the myometrium is designated as adenomyosis.[1] Although adenomyosis has been referred to as endometriosis interna, this term is no longer used because endometriosis and adenomyosis are unrelated disorders.[1]

The pathogenesis of endometriosis is controversial. The two principal histogenetic theories are (1) metastases of endometrial tissues to an ectopic location (metastatic theory) and (2) metaplastic development of endometrial tissue at the ectopic site (metaplastic theory).[1] Some clinical investigators favor the metastatic theory,[2-4] but most pathologists prefer the metaplasic theory.[5-8] In addition, other investigators favor a combination of the metastatic and metaplastic theories, postulating that endometriosis represents a metaplastic response to the irritative effects of endometrial tissue that has metastasized to ectopic sites.[9]

Since Lauchlan[10] first used the term "secondary müllerian system" to refer to all müllerian-type epithelium (including endometriotic lesions) located outside the cavities of the original müllerian ducts, many manifestations of müllerian-directed metaplasia and nonneoplastic proliferations (both epithelial and mesenchymal), which can be identified on or immediately beneath the ovarian surface, the pelvic peritoneum, and the omentum and in retroperitoneal lymph nodes, have been reported.[1,8] This evidence has demonstrated the müllerian-directed metaplastic potential of these tissues and supports the metaplastic theory of endometriosis. In addition, common epithelial tumors of the ovary are considered to be derived from the surface epithelium covering the ovary and from the underlying stroma.[11] Although the ovary is not of müllerian origin, the source of these neoplasms, namely, the surface epithelium, is derived from the coelomic epithelium, which in the embryo gives rise to the müllerian ducts. The latter form the fallopian tubes, uterine body, cervix, and possibly the upper part of the vagina and their large variety of epithelia. Therefore the histologic heterogeneity of the müllerian-type epithelium encountered in this group of tumors does not contradict their common origin. The common histogenesis of epithelial tumors of the ovary has been accepted by most authorities[11]; however, the metaplastic theory does not seem to be widely accepted as the basic concept in the pathogenesis of endometriosis. Therefore, from an embryologic standpoint, the importance of the secondary müllerian system in the pathogenesis of endometriosis will be discussed here.

Embryology of the female genital tract

At the end of the second week of embryonic life, the human embryo is a bilaminar oval disk, approximately 0.2 mm in diameter. The two lamina are the first two

germ layers. The dorsal layer is the ectoderm and the ventral layer, the first to differentiate, is the endoderm (Fig. 1, *A*). The third embryonic layer, the mesoderm, is induced by the endoderm from the ectoderm during the third week of embryonic life (Fig. 1, *B*). The mesoderm continues to proliferate, separating the ectoderm and the endoderm. By the end of the third week of embryonic life, an intramesodermal cavity develops in the lateral portion of the mesodermal layer on both sides of the disk. These bilateral intramesodermal cavities extend cephalad producing a continuous intramesodermal canal that extends along the anterior portion of the embryo. The mesodermal canal forms a cavity termed the coelomic cavity, which is destined to become organized into the pericardial, pleural, and peritoneal cavities (Fig. 1, *C*).[12,13] The coelomic cavity is lined by flat mesothelial cells that have epithelial-like features but have differentiated from the underlying stellate stromal cells.[12] The coelomic epithelium, that is, the peritoneum, is therefore a mesothelial epithelium that is derived from the mesenchyme immediately beneath it.[12] This raises the possibility that there is more intimate biological relationship between the epithelium and the stroma in the mesodermal system than is the case where ectodermal or endodermal epithelia are supported by mesodermal stroma.[12]

By the end of the fourth week, on each side of the posterior wall of the coelomic cavity, a vertical ridge (urogenital ridge) develops. Late in the fifth to sixth week of embryonic life, on the lateral surface of the urogenital ridge, the coelomic epithelium invaginates at several points and coalesces to form a tube termed the müllerian or paramesonephric duct (Fig. 1, *D*).[12,13] The duct extends caudally in the urogenital ridge immediately lateral to the wolffian duct. The paired müllerian ducts give rise to the fallopian tubes, the uterus, the cervix, and the upper vagina (Fig. 1, *E*).[12,13]

The müllerian duct, which is composed of a single layer of undifferentiated columnar epithelium supported by fibroblastic mesenchymal cells, gradually differentiates into ciliated columnar epithelium in the fallopian tube, endometrial glandular epithelium and stromal cells in the endometrium, and mucin-producing cells in the cervix. Ultrastructurally the undifferentiated columnar epithelium gradually accumulates a large amount of glycogen particles until 18 weeks' gestation. These glycogen particles disappear at 20 weeks; then the ciliated cells in the fetal fallopian tube and the secretory cells in the endometrium and cervix are identified.[14] Thereafter adult histology of tubal, endometrial, and endocervical epithelium[15] is recognized in the respective parts of the female genital tract. Therefore, as a result of local differentiation, the

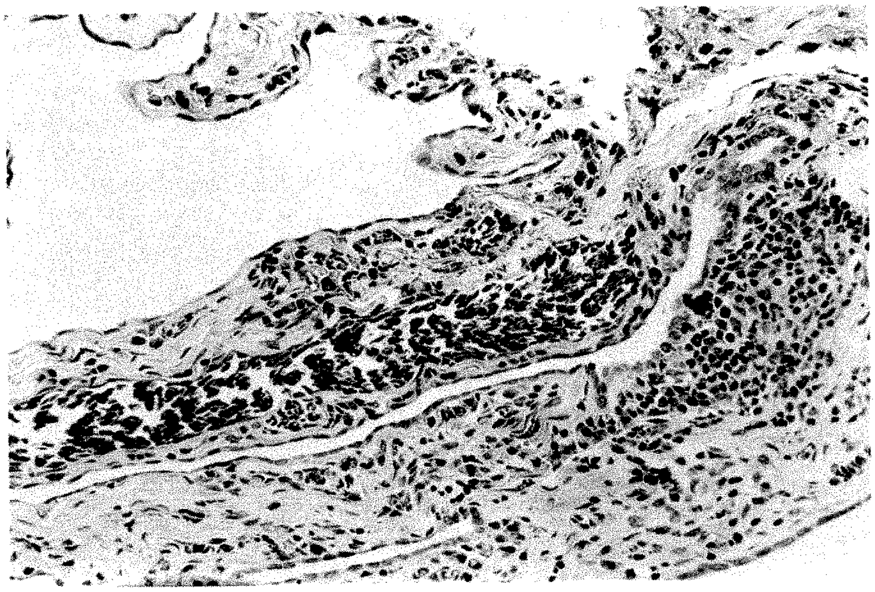

Fig. 2. Photomicrograph of omentum demonstrating increased cellular height of mesothelium. (Hematoxylin and eosin; original magnification ×200.)

differing adult histology of the tube, endometrium, and endocervix occurs.[14, 15] The mesenchymal cells and the müllerian epithelium also gradually differentiate into smooth muscle cells and endometrial stromal cells, resulting in the formation of the tubular muscular structure of the uterus and fallopian tubes.[16-18]

Localization of CA 125 in embryonic and adult tissues

CA 125 is an antigenic determinant recognized by the monoclonal antibody OC 125 against an ovarian cancer cell line (OVCA 433).[19] An assay of serum CA 125 has proved useful in the diagnosis and monitoring of patients with ovarian cancer.[20] However, serum CA 125 levels increase not only in women with other gynecologic malignancies[21] but also in women with benign conditions such as endometriosis[22] and pelvic inflammatory disease and during pregnancy.[23, 24] Immunohistochemically the CA 125 antigen is detected in coelomic epithelium and its derivatives such as the müllerian ducts of the fetus[25, 26] and müllerian-derived epithelia of the adult.[27, 28] More precisely CA 125 is present in fetal coelomic epithelium and its derivatives such as pleura, pericardium, peritoneum, ovarian surface epithelium, and müllerian ducts after 15 weeks' gestation. However, it is usually weakly positive for anti-CA 125 until 23 weeks' gestation.[25, 26] Thereafter CA 125 becomes strongly positive in müllerian-derived epithelia of the adult such as tubal, endometrial, and endocervical epithelium.[27, 28] Therefore CA 125 is considered a differentiation antigen associated with fetal coelomic epithelium and its derivatives, which are believed to be derived from the mesoderm of germ cells.[25, 26]

The expression of CA 125 during the fetal period and in the adult strongly suggests that the coelomic epithelium–related tissues (pleura, pericardium, peritoneum, and ovarian surface epithelium) and the müllerian-derived epithelia of the adult (tubal, endometrial, and endocervical epithelium) have a shared embryologic ancestry.

Secondary müllerian system

Awareness of the embryology of the peritoneal and müllerian duct epithelium led Lauchlan[10] to postulate that tissues derived from coelomic epithelium and its accompanying mesenchymal cells, referred to as the "secondary müllerian system," have the potentiality to differentiate into müllerian-directed epithelium and stroma.

Both on and immediately beneath the ovarian surface, the pelvic peritoneum, and the omentum, and in retroperitoneal lymph nodes, müllerian-directed metaplasia (both epithelial and mesenchymal) can be identified. The most common type of epithelial differentiation is tubal-type epithelium composed of ciliated cells without endometrial stromal cells, and this type is usually called endosalpingiosis.[29-32] In the omentum, when the mesothelium begins to appose, the cellular height of the mesothelium increases and shows a focal epithelioid architecture (Fig. 2). Thereafter the epithelium may invaginate and remain as an inclusion, and focal differentiation of the ciliated cells can be observed among the epithelioid cells (Fig. 3). If an inclusion of the ovarian surface epithelium is formed, the mesothelium-like ovarian surface epithelium gradually increases in cellular height and shows ciliated differentiation in the inclusion (Fig. 4). Endometrial-type epithelium with endometrial stroma is often observed

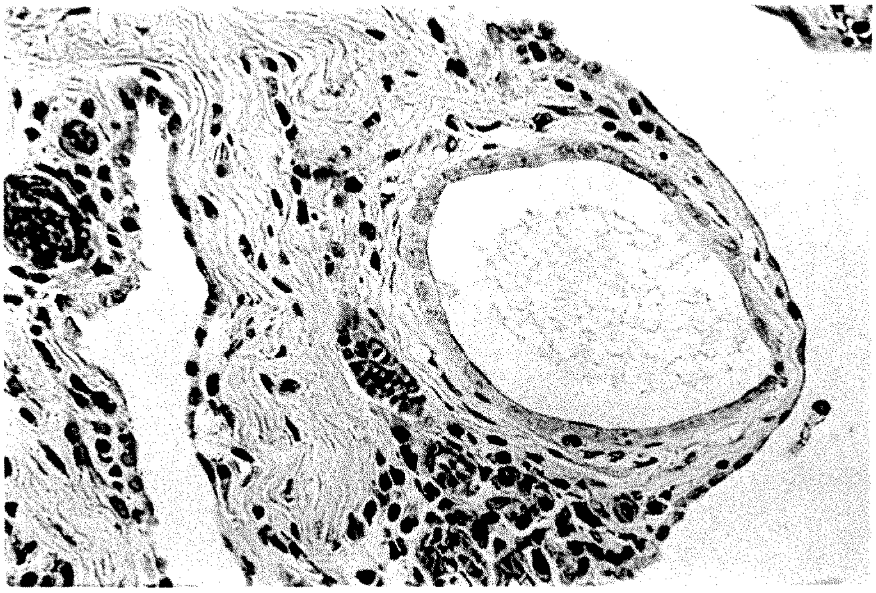

Fig. 3. Photomicrograph of omentum demonstrating glandular structure with focal ciliated differentiation. (Hematoxylin and eosin; original magnification ×400.)

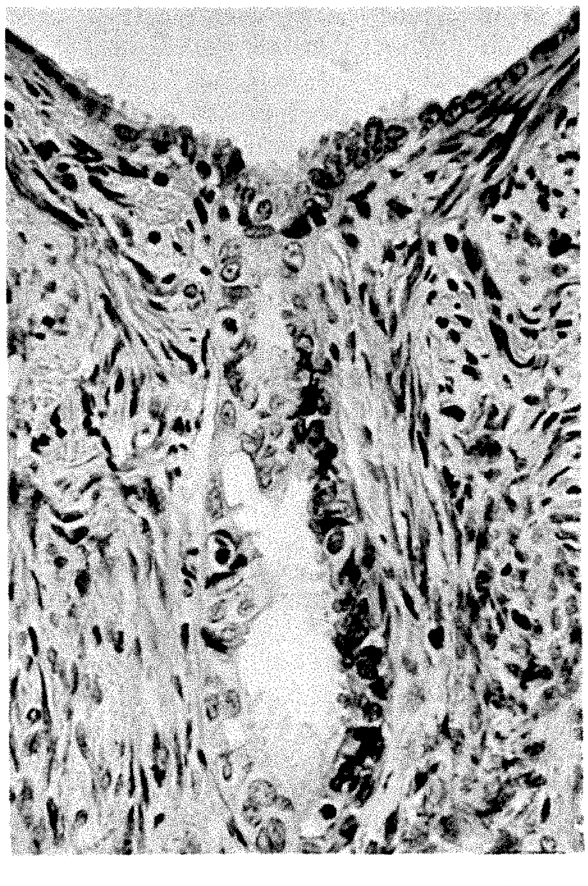

Fig. 4. Ovarian inclusion demonstrating gradual differentiation of surface epithelium into ciliated cells. (Hematoxylin and eosin; original magnification ×400.)

close to or intermingled with tubal-type inclusions. Endometrial-type epithelium without the appearance of endometrial stroma is also seen frequently. However, transformation of ovarian surface epithelium into endometrial-type epithelium with endometrial stroma and hemosiderin-laden macrophages can also occur (Fig. 5). Transformation of mucinous-type epithelium, although considerably less common,[1] occurs in the ovaries and in the retroperitoneal space.[33] In addition, adenomatoid tumor–like structures with ciliated or mucinous cells have also been observed in subperitoneal nodules experimentally induced by administration of sex steroids.[34]

The superficial stroma of the ovary is composed of the mesenchyme and the coelomic epithelium. This embryonic kinship allows the peculiar ability of the superficial ovarian cortex,[35, 36] the peritoneum,[37] and the uterine subserosa to undergo a decidual reaction during pregnancy in response to the prevailing hormonal milieu. Moreover, both the fallopian tube and the cervical stroma exhibit a focal decidual reaction during pregnancy, which is morphologically identical to that occurring in the endometrium. Furthermore, smooth muscle differentiation occurs in the peritoneum[38] and the superficial stroma of the ovary.[39] Smooth muscle cell differentiation is involved in leiomyomatosis peritonealis disseminata.[37, 38, 40, 41] Differentiation of the subcoelomic mesenchyme in the direction of smooth muscle, with the formation of multiple tumor-like nodules in the peritoneum including the ovarian surface, is the

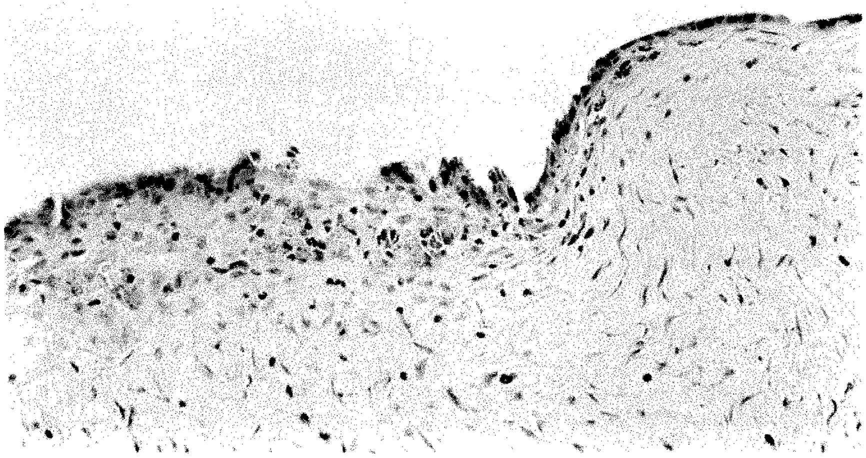

Fig. 5. Row of ovarian surface epithelium and endometrioid epithelium with endometrial stroma and hemosiderin-laden macrophages. (Hematoxylin and eosin; original magnification ×200.)

purported pathogenesis of leiomyomatosis peritonealis disseminata.[10, 11] Some degree of smooth muscle differentiation can sometimes be seen around inclusion cysts and endometriotic lesions.[39] The components of the latter are endometrial-type epithelium and stroma surrounded by smooth muscle resembling the architecture of the uterus.[39]

The incidence of tubal-type epithelium was assessed by Zinsser and Wheeler[30] who prospectively studied the omentum from surgical and autopsy material in both women and men; lesions were found only in surgically removed omenta from women (in 25.7% of cases) and were never identified in men. Müllerian-directed metaplasia is generally considered an acquired property; the lesions have not been described in premenarcheal girls.[42] It is likely that the lesions are induced by changes in the hormonal milieu that follow puberty. In addition to being hormonally induced, the lesions show variable hormone dependency and sensitivity. Müllerian-directed metaplasic lesions atrophy after menopause and may eventually degenerate and be resorbed.[30, 31]

Comment

Several reports in the literature support the concept of a metastatic theory of endometriosis.[1-4] Sampson[13] proposed that endometriosis is a consequence of reflux of endometrial tissue through the fallopian tubes by a process of retrograde menstruation, with subsequent implantation and growth on peritoneal surfaces.[13] Endometriosis within scars after uterine operations may be the result of iatrogenic implantation of endometrial tissue during surgery.[9] In addition, the presence of endometriosis in certain distant sites (e.g., lungs, skeletal muscle, subarachnoid space, and kidneys) is most easily explained by the theory of lymphatic and vascular metastasis.[14] Endometriosis within lymph nodes has also been explained as the result of lymphatic spread.

However, normal endometrium that can metastasize is essential for the metastatic theory to be valid. The metastatic theory cannot explain the finding of endometriosis in subjects in whom metastasis of normal endometrium could not occur or is highly unlikely, such as patients with Rokitansky-Kuster-Hauser syndrome, Turner syndrome, and pure gonadal dysgenesis who are amenorrheic and have hypoplastic uteri[15-17] and men with endometriosis of the bladder, prostate, scrotum, and abdominal wall.[18-51]

In most cases a process of retrograde menstruation may have an important role in the establishment of endometriosis. However, we cannot forget cases of endometriosis in which retrograde menstruation does not occur. Consequently the concept that coelomic epithelium–derived tissues have the potentiality to differentiate into müllerian-directed epithelium always lies a priori in the pathogenesis of endometriosis. On the basis of this concept, the influence of unknown factors that may be carried by a process of retrograde menstruation should be taken into account in the pathogenesis of endometriosis. The cases of leiomyomatosis peritonealis disseminata indicated that there is an individual sensitivity of subperitoneal mesenchymal cells to reproductive steroids.[41] Some cases of leiomyomatosis peritonealis disseminata occurred during pregnancy or use of oral contraceptives and regressed soon after delivery or discontinuation of drugs; but other cases, discovered in persons with normal ovarian cycles, regressed with castration.[41] Therefore individual sensitivity of coelomic epithelium–derived tissues to reproductive steroids should also be considered when trying to explain the pathogenesis of endometriosis. Indeed the metastatic theory is a fascinating one, but further research based on the metaplastic potentiality of the secondary müllerian system into müllerian-directed structures is necessary to elucidate the pathogensis of this enigmatic disease.

Ultrastructural study of glandular epithelium in adenomyosis in comparison with those of proliferative endometrium and well-differentiated endometrial cancer

Takashi Hayata, MD
Oita, Japan

Adenomyotic glandular tissue from five patients underwent electron microscopic investigation to observe its ultrastructural characteristics. The adenomyotic epithelium was compared with that of proliferative normal epithelium (two patients) and well-differentiated endometrial adenocarcinoma (two patients). The results revealed that morphologically the adenomyotic glandular epithelium is somewhat less differentiated than proliferative endometrium and that its cytoplasmic organelles have some similarities with those of endometrial cancer. Whether these similarities predispose the adenomyotic glandular tissue to malignant degeneration remains to be elucidated. (AM J OBSTET GYNECOL 1991;165:225-8.)

Key words: Adenomyosis, endometriosis, electron microscopy

The histogenesis of adenomyosis is still unknown at present. Ultrastructural observations of adenomyotic glandular epithelium would probably give some insight into its neoplastic characteristics[1]; consequently, I carried out electron microscopic studies to compare adenomyotic glandular epithelium with proliferative phase endometrium and well-differentiated endometrial adenocarcinoma.

Material and methods

Five patients with adenomyosis in the proliferative phase whose ages ranged between 30 and 52 years were selected for this study (Table I). Patients (cases 1 and 2) had surgery on the eighteenth and sixteenth days of the menstrual cycle, respectively. Both the orthotic and heterotopic glandular tissue were in the proliferative phase. Patients (cases 3, 4, and 5) had surgery during the secretory phase of the menstrual cycle. In these patients the endometrium was in the late secretory phase; however, the adenomyotic glandular tissue showed proliferative phase characteristics. Dating of tissue was carried out according to Noyes et al.[2] Well-differentiated endometrial adenocarcinoma tissue obtained from two other patients was also examined.

Electron microscopic findings in adenomyosis

Case 1. Nuclei were round with a smooth nuclear membrane and finely distributed chromatin. Nucleoli or chromatin clumps were not observed. The cytoplasm was either clear or dark. Mitochondria were round with some irregularities. Free ribosomes and the microfibrillar structure were moderately developed. The rough endoplasmic reticulum and glycogen granules were scarce. Extracellular structures, such as desmosomes, interdigitations, and microvilli, were relatively well developed.

Case 2. Nuclei were basically oval with a smooth nuclear membrane. Nucleoli, if present, had an irregular shape, and there was only one per cell. The chromatin was distributed diffusely. Free ribosomes were abundant, and the rough endoplasmic reticulum was moderately developed. Mitochondria were round with some irregularities. Glycogen granules were not found, and the extracellular structures were almost the same as in case 1.

Case 3. Nuclei were oval with a smooth nuclear membrane and fine chromatin. Nucleoli, if present, were smooth, and there was only one per cell. Mitochondria were oval with some irregularities. The rough endoplasmic reticulum, ribosomes, and the microfibrillar structure were moderately developed. Glycogen granules were scarce. Desmosomes were abundant, whereas interdigitations were poorly developed.

Case 4. Nuclei were oval with an extremely smooth nuclear membrane. If nucleoli were present, there was only one per cell, and they had a somewhat irregular morphologic appearance. Nuclear chromatin was finely distributed. The rough endoplasmic reticulum and free ribosomes were well developed. Mitochondria were oval with moderate irregularities. Lysosomes were not found and glycogen granules were scarce. The extracellular structures, such as microvilli, were relatively well developed.

Case 5. Nuclei were round with none or one nucleolus and a smooth nuclear membrane. Notably, the chromatin was attached to the nuclear membrane. The rough endoplasmic reticulum was scarce. Free ribosomes were moderately developed. Mitochondria were round with moderate irregularities. Lysosomes were abundant, but glycogen granules were not found. Interdigitations were strickingly abundant. The Golgi apparatus but not myelin body was found in all cells examined in the five cases studies.

Electron microscopic findings in proliferative phase endometrium

The proliferative phase endometrium of cases 1 and 2 was examined. The most common findings were as follows.

The cylindric epithelium was arranged tightly and piled up in some parts. The nucleoli were situated near the basement membrane and were clearly observed. Nucleoli were either rodlike or oval, with the chromatin scattered and attached to the nuclear membrane. Chromatin was present in moderate amounts. There was one smooth nucleolus and sometimes two. Mitochondria were rodlike or oval; the rough endoplasmic reticulum was elongated and moderately developed. Free ribosomes and lysosomes were also moderately developed. Glycogen granules were present in small amounts, and the Golgi apparatus was moderately developed. The microfibrillar structure was scarce, and the microvilli were developed but with slight length irregularities. Myelin bodies were not observed.

Electron microscopic findings in well-differentiated adenocarcinoma of the endometrium

Well-differentiated endometrial adenocarcinoma tissue from two other patients was also examined. In these tissues nuclei of an extremely irregular shape and with coarse chromatin were found. The rough endoplasmic reticulum was more abundant than proliferative endometrium or adenomyotic glandular epithelium. Free ribosomes were also abundant. Mitochondria were very irregular, especially the mitochondrial crista. Lysosomes were numerous and of different sizes. The Golgi apparatus was poorly developed. Microfibrillar structures were abundant, and myelin body was observed in some cells. Desmosomes and interdigitations were present, but they were not always observed. Microvilli were quite numerous and of various sizes.

Table II. Electron microscopic appearance of the nucleus in the three tissue categories studied

Nuclear	*Proliferative endometrium*	*Adenomyotic gland*	*Endometrial adenocarcinoma*
Shape	Rod to oval	Round to oval	Elongated
Chromatin	Scattered, adherent to nuclear membrane	Scattered, fine	Coarse
Nucleoli	1-2, regular	0-1, irregular	Increased, bizarre
Membrane	Slightly irregular	Extremely smooth	Very irregular

Table III. Electron microscopic appearance of the cytoplasm in the three tissue categories studied

Cytoplasmic	*Proliferative EM*	*Adenomyotic gland*	*Endometrial adenocarcinoma*
Rough ER	+ +	+ ~ + + +	+ + +
Free ribosomes	+ +	+ + ~ + + +	+ + +

Comparison of the adenomyotic glandular epithelium ultrastructure with that of the proliferative endometrium and well-differentiated endometrial adenocarcinoma

Nucleous. Electron microscopic findings in the nucleous in the three types of tissue are summarized in Table II. In adenomyotic tissue, the nuclear membrane was distended and smooth in four of five cases. The nuclei were round or oval. Chromatin was more finely distributed in adenomyotic glandular epithelium than in proliferative endometrium or endometrial adenocarcinoma. If the nucleolus was present, there was only one per cell and showed some irregularities.

Therefore one can distinguish the adenomyotic glandular epithelium from the well-differentiated endometrial adenocarcinoma because of the coarse chromatin and the irregularities of the nuclear membrane found in the latter.

Cytoplasm. Electron microscopic findings in the cytoplasm of the three types of tissue are summarized in Table III. In the adenomyotic glandular epithelium, the degree of development of cytoplasmic organelles, such as rough endoplasmic reticulum, free ribosomes, and microfibrillar structure, is between that of proliferative endometrium and well-differentiated endometrial adenocarcinoma. As shown in Table III, some structures seem closer to those of proliferative endometrium, whereas others have more characteristics in common with structures in the well-differentiated endometrial adenocarcinoma.

Comment

I examined the adenomyotic glandular epithelium to study its ultrastructural characteristics and compared them with the electron microscopic findings in normal proliferative endometrial epithelium and those of well-differentiated endometrial adenocarcinoma.

Characteristics of the endometrium ultrastructure in women with a normal cycle are well documented. Ultrastructural differences of the endometrium at different phases of the menstrual cycle are well established; however, ultrastructural diversity of the endometrium in the same phase has also been observed. This diversity depends mainly on the depth of the glands, that is, the depth of the functional and basal layers of the endometrial epithelium. I focused my observations on the surface epithelium inside the lumen and examined the tissue from five patients with different menstrual cycles to ascertain the common characteristics of the heterotopic endometrium when under different hormonal stimulation.

Nilsson[3] reported that few differences exist between normal glandular epithelium and endometrial adenocarcinoma in the early stage. On the other hand, Gompel[4] studied 14 cases of endometrial cancer by electron microscopy and compared those findings with the ultrastructural characteristics of normal glandular epithelium. However, although he found various morphologic changes in endometrial cancer, he could not define those changes as specific for cancer. A year later Thrasher and Richart[5] reported that endometrial adenocarcinoma cells had abnormal nuclei and nucleoli and that the nuclear bodies were similar to those previously described in the neoplasms of other organs. In this study I was able to point to the morphologic characteristics inherent to endometrial adenocarcinoma compared with those of normal endometrium.

In an interesting report Cummins et al.[6] compared endometrioid adenocarcinoma possibly arising in endometriosis with normal endometrium and endometrial adenocarcinoma; they concluded that it was difficult to distinguish between both tissues under electron microscopic examination. In addition, these two tissues had characteristics similar to those of orthotic proliferative endometrium. Kumar and Anderson[7] reported one case of multicentric adenocarcinomatous changes in endometriosis interna and called it malignant adenomyosis. I also demonstrated the presence of adenomyosis intermingled with endometrial cancer in eight patients.[8]

In conclusion, the ultrastructural findings in adenomyotic glandular epithelium reported herein were different from those of proliferative endometrium, and cytoplasmic organelles have some similarities with those of well-differentiated endometrial adenocarcinoma; however, as yet, no proof has been offered that these similarities predispose the adenomyotic endometrium to malignant degeneration. Unlike normal endometrial tissues, the morphologic features of adenomyosis could be related to its invasive properties. Nevertheless, it remains to be clarified whether these features are essential changes of the adenomyotic glandular epithelium or whether they simply reflect morphologic manifestations arising as a result of the ectopic growth of endometrial cells.

Relationship between the onset of dysmenorrhea and histologic findings in adenomyosis

Masato Nishida, MD, PhD
Tsukuba, Japan

An attempt was made to evaluate the relationship between histologic findings of adenomyosis and onset of dysmenorrhea. Thirty-four cases of histologically diagnosed adenomyosis were investigated in this study. One large sample cut along the longitudinal axis was made and examined to evaluate the histologic parameters and CA 125 levels. Dysmenorrhea was classified into grade I (absent or mild) and grade II (severe). Localization of adenomyosis was divided into type I, adenomyosis continuous from the surface endometrium (29 cases), and type II, adenomyosis present on the serous side of the uterus and not continuous from the surface endometrium (five cases). We made type I adenomyosis, which included 13 cases of grade I and 16 cases of grade II, the focus of our investigation. The parameters that correlated with dysmenorrhea were the number of islands of adenomyosis and glands, distance of invasion, relative rate of invasion, and CA 125 levels. The differences between grades I and II were apparent in the frequency distribution tables, with dysmenorrhea occurring at invasion rates of 80% and greater. (AM J OBSTET GYNECOL 1991;165:229-31.)

Key words: Adenomyosis, onset of dysmenorrhea, histologic findings

Uterine adenomyosis is often associated with dysmenorrhea and is usually treated surgically to relieve symptoms. Dysmenorrhea and swelling of the uterus are often pathognomonic of adenomyosis, affecting all layers of the uterus.[1] However, adenomyosis is often associated with uterine myoma[1-3] and is frequently discovered incidentally in the uterus of patients having surgery for uterine myoma as a result of histopathologic examination. Some patients with this condition complain of dysmenorrhea, whereas others have no symptoms. Therefore it is possible to examine the relationship between histologic findings in adenomyosis and the presence of dysmenorrhea by comparing symptoms and histologic findings in these patients.

In the present study the correlation between histologic findings in adenomyosis and the onset of dysmenorrhea was examined.

Material and methods

Thirty-four patients were entered into this study; 9 had adenomyosis only and 25 had adenomyosis associated with uterine myoma. The diagnosis was made on the basis of macroscopic findings obtained during surgery and histologic examination of tissue samples. Patients were between 40 and 59 years old (mean, 46.7 ± 4.5 years).

The uteri excised during surgery were longitudinally incised along the anterior wall and fixed in 10% formalin. Just one large sample cut along the longitudinal axis was stained with hematoxylin and eosin and examined under an optical microscope to examine the following parameters (Fig. 1): (1) localization of adenomyosis—there were two types of adenomyosis: type I (adenomyosis continuous from the surface endometrium) and type II (adenomyosis present on the serosa of the uterus and not continuous from the surface endometrium); (2) thickness of uterine muscle; (3) number of islands of adenomyotic lesions (including glands and stroma); (4) number of glands; (5) mean number of glands contained in one island of adenomyosis; (6) distance between surface endometrium and the deepest portion of islands in the invaded tissue; (7) ratio of the depth of adenomyosis to uterine muscle thickness; (8) status of adenomyotic lesions, that is, lesions were classified as being in the proliferative or secretory phase; (9) presence or absence of hemorrhage in adenomyotic lesions; and (10) preoperative CA 125 levels.

Dysmenorrhea was classified into the following two categories: grade I (dysmenorrhea is absent or slight) and grade II (marked dysmenorrhea is present or analgesics are required during menstruation).

Results

Histologic findings and CA 125 levels

Localization of adenomyosis uteri. Types I and II were found in 29 and 5 cases, respectively. Patient ages, number of islands of adenomyosis and glands, dysmenorrhea, and CA 125 blood levels in the type of adenomyosis are shown in Table I. There were significant differences between the two types in the number of islands and glands and CA 125 levels in the blood. The incidence of dysmenorrhea was significantly lower in

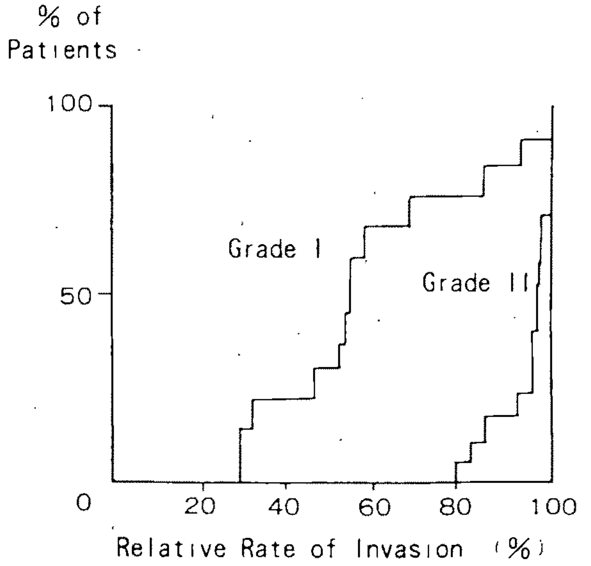

Fig. 2. Relative cumulative frequency distribution of patients.

Table I. Outcome data for localization of adenomyosis

Data	*Type I* (*n* = 29)	*Type II* (*n* = 5)
No. of islands	134.7 ± 122.0	15.2 ± 16.6
No. of glands	623.1 ± 657	99.8 ± 124.9
Dysmenorrhea		
Grade I (No.)	13	4
Grade II (No.)	16	1
CA 125 value (U/ml)	109.4 ± 137.9 (5.2-579.0)*	30.2 ± 30.8 (6.0-84.0)*
Age (yr)	46.9 ± 4.7	45.8 ± 2.4

Data are mean ± SD.
*Lower and upper values.

type II. There were no significant differences in patient ages. Only the 29 patients with type I adenomyosis were evaluated in the other parameters (Table II).

Muscle layer thickness. Uterine muscle layer thickness was comparable between grade I (42.1 ± 20.2 mm [mean ± SD]) and grade II (45.0 ± 15.4 mm).

Number of islands of adenomyosis. The total number of islands per section of uterine muscle layer was significantly greater for grade II (197.7 ± 125.9) than for grade I (58.6 ± 60.3) ($p < 0.01$).

Number of glands. The number of glands per section of uterine muscle was significantly greater for grade II (840.4 ± 629.2) than for grade I (255.6 ± 612.4) ($p < 0.05$).

Mean number of glands per island of adenomyosis. The mean number of glands per island of adenomyosis was comparable for grades I (6.3 ± 6.8) and II (5.1 ± 4.6).

Distance between the surface endometrium and the deepest portion of the adenomyotic lesion. The distance between the surface endometrium and the deepest portion of the adenomyotic lesion was significantly greater for grade I (42.9 ± 16.1 mm) than for grade II (24.9 ± 16.6 mm) ($p < 0.01$).

Ratio of the depth of adenomyosis to uterine muscle thickness. The degree of invasion estimated based on the depth/muscle layer thickness × 100 (percent) was significantly greater for grade II (94.3% ± 6.7%) than for grade I (57.9% ± 23.3%) ($p < 0.01$).

Status of adenomyotic lesions. There were no significant differences between grades I and II.

Presence or absence of hemorrhage from adenomyotic lesions. There were no significant differences between grade I and II.

CA 125 levels. Preoperative CA 125 levels in the blood were significantly higher for grade II (162.2 ± 161.0 U/ml; range, 6 to 579 U/ml) than for grade I (37.9 ± 44.9 U/ml; range, 5.2 to 60 U/ml) ($p < 0.02$).

Frequency distribution analyses. Frequency distribution tables were prepared with respect to the items that showed significant differences between the two groups to determine the borderline at which grade I dysmenorrhea progresses to grade II dysmenorrhea.

Number of islands of adenomyotic lesions. All eight patients with 200 or more islands of adenomyotic lesions were in grade II. However, 6 of 16 patients (37.5%) with less than 50 adenomyotic lesions were also in grade II, and no clear borderline could be determined.

Number of glands. Ten of the 13 patients with 500 or more glands were in grade II. However, no clear borderline could be determined because seven patients with less than 500 glands were also in grade II.

Distance between the surface endometrium and the deepest portion of the adenomyotic lesion. Five of the six patients with distances between the surface endometrium and the deepest portion of the adenomyotic lesion of 50 mm and over were in grade II. However, the borderline

Table II. Outcome data for grade of dysmenorrhea

Data	*Grade I* *(n = 13)*	*Grade II* *(n = 16)*	*p*
Muscle layer thickness (mm)	42.1 ± 20.2	45.0 ± 15.4	NS
No. of islands	58.6 ± 60.3	197.9 ± 125.9	<0.01
No. of glands	255.6 ± 612.4	840.4 ± 629.2	<0.05
Mean No. of glands	6.3 ± 6.8	5.1 ± 4.6	NS
Depth of invasion (mm)	24.9 ± 16.6	42.9 ± 16.1	<0.01
Relative rate of invasion (%)	57.9 ± 23.3	94.3 ± 67.0	<0.01
CA 125 (U/ml)	37.9 ± 44.9 (5.2-60.0)*	162.2 ± 161.0 (6.0-579.0)*	<0.02

Data are mean ± SD.
*Lower and upper values.

between grades I and II could not be drawn based on absolute glandular depth.

Ratio of the depth of adenomyosis to muscle layer thickness. The frequency distribution table prepared regarding the degree of glandular invasion showed that all 19 patients with invasion rates of 80% and over were grade II. A relative cumulative frequency distribution table was then prepared (Fig. 2). Differences between grades I and II were apparent in this table, with dysmenorrhea occurring at invasion rates of 80% and greater.

Comment

Since the report by Cullen,[4] the histogenesis of uterine adenomyosis has been explained as a deep proliferation of the normal endometrium. It is well-known that uterine adenomyosis causes dysmenorrhea and occurs mainly in multiparous women,[1,3,5] in particular in those aged 35 years and over.[2,5,6] However, adenomyosis is often associated with uterine myoma and is often discovered incidentally in patients undergoing surgery for uterine myoma.[1-3] Dysmenorrhea may not necessarily be present in these patients, and it may be absent despite the presence of adenomyosis. Therefore it is likely that dysmenorrhea occurs when adenomyosis has progressed to some extent.

In the present study we determined the relationship between histologic findings in adenomyosis and the onset of dysmenorrhea based on histologic examination of adenomyosis.

The 29 patients with histologic evidence of adenomyosis, 16 with dysmenorrhea and 13 without dysmenorrhea, were compared. Significant differences were observed between the two groups in the number of islands of adenomyosis, number of glands, distance between the surface endometrium and deepest adenomyotic lesion, and the ratio of the depth of adenomyosis to uterine muscle thickness. There were no significant differences between the two groups in muscle layer thickness, number of glands per island of adenomyosis, status of adenomyosis, or the presence or absence of hemorrhage in adenomyosis. CA 125 levels were correlated with the severity of dysmenorrhea.

Frequency distribution tables were prepared for the items that showed close correlation with the severity of dysmenorrhea to determine the borderline at which dysmenorrhea occurs. No clear borderline was observed with respect to the number of islands of adenomyotic lesions and glands or depth of adenomyosis. However, a clear borderline was found regarding the extent of glandular invasion, with dysmenorrhea occurring when glandular invasion exceeds 80% or more of the myometrium. This means, for example, that dysmenorrhea occurs when the depth of invasion exceeds 1.6 cm in patients with a 2 cm thick muscle layer. In patients with a 5 cm thick muscle layer, symptoms occur when the depth of invasion exceeds 4 cm. This finding suggests that dysmenorrhea is not only caused by increases in the amount or size of adenomyosis in the uterine muscle layer but also by the extent of muscle invasion.

In this study population, the incidence of dysmenorrhea was not high in patients with adenomyotic lesions only on the serous side, which suggests that invasion up to the perimetrium is not the only requirement for the onset of dysmenorrhea. Dysmenorrhea probably occurs when the volume of adenomyotic lesions as a percentage of the total uterine volume exceeds a certain threshold. Dysmenorrhea appears to be the result of tonic stimulation of the entire uterus by adenomyosis. This stimulation seems to be induced when the depth of invasion exceeds 80% of the total muscle layer.

Animal model of uterine adenomyosis: Is prolactin a potent inducer of adenomyosis in mice?

Takao Mori, PhD, Tippawan Singtripop, MSc,* and Seiichiro Kawashima, PhD
Tokyo, Japan

Uterine adenomyosis is a benign lesion but a serious disease for women, because the symptoms are characterized by abnormal bleeding, pain, cramps, and sterility. Thus elucidation of the mechanisms involved in the development of the disease would contribute to improved management and treatment and prophylaxis of this lesion. A mouse model, in which ectopic pituitary isografting is associated with an increase in the plasma level of prolactin, is useful for a rapid and frequent induction of uterine adenomyosis and can be used to study the origin of this lesion. (Am J Obstet Gynecol 1991;165:232-4.)

Key words: Adenomyosis, mouse, animal model, prolactin

Uterine adenomyosis is a benign pathologic disorder characterized by ectopic growth of the endometrial tissues, stroma, or glands or both into and beyond the myometrium. Spontaneous development of adenomyosis with advanced age has been reported in several species of animals, including nonhuman primates.[1-6] Many research reports deal with the development of uterine lesions, but almost all have concentrated on the development of uterine cancer. However, uterine adenomyosis, which is considered one of the causes of abnormally prolonged and profuse bleeding, cramps, and sterility in humans and animals,[3, 7] has not attracted much attention. Presently the endocrine mechanisms responsible for the genesis of adenomyosis are not well understood. Therefore it would be of great value to establish an animal model for uterine adenomyosis to study the mechanisms involved in its development; a better understanding of the origin and pathophysiology of adenomyosis will contribute to improved management and treatment, as well as prophylaxis, of this lesion in humans.

We have found that ectopic pituitary transplantation results in an early development of adenomyosis and at a high incidence in mice; in mice adenomyosis was associated with an elevated plasma level of prolactin.[8-12] These findings led us to believe that in mice chronic hyperprolactinemia is a major hormonal factor in the genesis of adenomyosis. This article reviews experimental methods for induction of adenomyosis and discusses the mechanisms of the development of this human disease based on data obtained from animal models.

Experimentally induced adenomyosis

The most commonly used method for the induction of adenomyosis is long-term estrogen therapy (usually more than 6 months). A pioneering report on the development of adenomyosis after long-term estrogen treatment was published in 1935[13]; mice were treated with estrogen for more than 8 months. After this finding, prolonged treatment with estrogen was established as an effective method for the induction of adenomyosis in mice,[14, 15] guinea pigs,[16, 17] rabbits,[18] and monkeys.[19, 20] It is well known that normal and abnormal proliferation of uterine tissues are mainly under the control of ovarian steroid hormones (estrogen and progesterone). Furthermore, Ostrander et al.[21] found a high incidence of adenomyosis in newborn mice treated with diethylstilbestrol in combination with progesterone and also in adult mice treated with progesterone plus estrogen. However, subcutaneous implantation of progesterone alone also enhanced the development of adenomyosis in mice,[21-23] suggesting that a high level of circulating progesterone is also a favorable factor for the genesis of this lesion.

Nevertheless, we recently reported that treatment with prolactin during the neonatal period (1 to 14 days of age) or young adult life (40 to 79 days of age) enhanced the development of adenomyosis in mice.[24] In addition, the administration of dopamine antagonists, which are potent enhancers of pituitary prolactin release, resulted in a high incidence of adenomyosis in mice (Singtripop et al. Unpublished data). These results strongly suggest that prolactin plays a key role in the development of uterine adenomyosis.

Moreover, prenatal exposure of mice to diethylstilbestrol resulted in a higher incidence of adenomyosis at advanced ages.[25-27] Prenatal and neonatal expo-

sure to estrogen or diethylstilbestrol results in a hormonal imbalance because of the altered function of the hypothalamo-hypophysial-ovarian axis,[28, 29] which may contribute to the development of adenomyosis. In contrast, it has been reported that similar neonatal treatment of mice with estrogen failed to induce adenomyosis, whereas in untreated control mice adenomyosis developed at an advanced age.[30] It is well known that decreased responsiveness to the growth-promoting effect occurs in the uterus of mice treated perinatally with estrogen.[28, 29] Thus it is also plausible that a decreased sensitivity of the uterus to estrogen could result in a low incidence of adenomyosis.

We have found that in mice an ectopic isograft of an anterior pituitary gland into the uterus induces adenomyosis at an early stage and at a high incidence; in this case adenomyosis was always associated with hyperprolactinemia.[8-12, 31] In these studies adenomyosis could be induced within a month after grafting although there were some strain differences regarding the latency period of development.[32] Huseby et al.[33, 34] confirmed our findings regarding the effect of pituitary grafting in mice and reported a significant rise in the serum level of progesterone in addition to that of prolactin. These findings imply that prolactin may play an important role in the development of adenomyosis, although a synergistic effect of progesterone and estrogen with prolactin cannot be excluded.

Histogenesis of adenomyosis in mice

This new method for the induction of adenomyosis by pituitary grafting[8-12] makes it possible to examine the histogenesis of adenomyosis because of the extremely short latency period between induction and development of the lesion. The earliest observable histologic change in the uterus is the infiltration of endometrial stromal cells into the inner myometrium, along the blood capillaries or lymphatic vessels. After invasion by a large number of stromal cells, uterine glands track the routes of the stromal cells and translocate into the musculature. The aberrant endometrial tissues then reach the connective tissue space between the inner and outer smooth muscle layers. Associated with these changes, the inner smooth muscle bundles of the myometrium become loosened and thinner.

Electron microscopy has revealed that noticeable changes in the morphology and arrangement of smooth muscle cells take place.[35, 36] The smooth muscle cells of the myometrium become markedly loosened unlike the muscle cells running concentrically around the uterine axis in normal control mice. In addition, muscle cells become irregular in shape and are markedly reduced in size, which result in wider intercellular spaces than those in normal control mice. Disintegration of the muscle layer, scantiness of cell organelles, and pyknosis of muscle cells are frequently observed in adenomyotic areas. These findings indicate that the first step, invasion of the myometrium by endometrial tissues, is caused by the degeneration of the muscle layer and that in the normal state the muscle layer protects tissues from invasion by proliferating endometrial tissue into the musculature.[35, 36]

Causes of the development of adenomyosis

As previously mentioned, we found that in mice ectopic isograft of the anterior pituitary gland induces adenomyosis at an early stage and at a high incidence; moreover, the development of adenomyosis was always associated with hyperprolactinemia.[11, 12] Furthermore, the spontaneous development of adenomyosis with advanced age could be prevented by the administration of bromocriptine, a potent suppressor of pituitary prolactin release, which was administered only for 4 weeks beginning at 4 weeks of age.[37, 38] In addition, the administration of prolactin during young adult life resulted in a high incidence of adenomyosis,[24] and the administration of dopamine antagonists, which are potent inducers of pituitary prolactin release, also enhanced the development of adenomyosis. All these findings are in agreement with our hypothesis that prolactin is the primary hormone involved in the development of adenomyosis in mice.

It is evident that prolonged treatment with estrogen results in a high incidence of adenomyosis. Since estrogen is a potent stimulant of pituitary prolactin secretion, long-term treatment with estrogen implies a possible participation of prolactin in the genesis of adenomyosis. In this respect, Ostrander et al.[21] claimed that the effect of prolonged treatment with progesterone, alone or in combination with estrogen, was not indicative of any role of prolactin in the genesis of adenomyosis, because progesterone prevented estrogen-induced prolactin elevation in rats. However, it is well known that prolactin stimulates progesterone secretion from the ovary, and it further enhances the effect of progesterone on the target cells,[39] perhaps through the modulation of progesterone receptor activity.

On the contrary, it has been reported that prolactin exerts a marked inhibitory effect on oxytocin-induced myometrial contraction both in rats primed with estrogen and progesterone[40] and in pregnant rabbits.[41] These findings indicate a close relationship between prolactin and function of the myometrium and suggest that prolonged exposure of the musculature to prolactin might cause myometrial degeneration as observed by electron microscopy.[35, 36] The degeneration of the myometrium may be responsible for the invasion by endometrial tissue into it; prolactin directly affects the myometrium and leads to the degeneration of muscle cells. In conclusion our mouse model of uterine adenomyosis strongly suggests that prolactin is a trigger in the genesis of adenomyosis and that estrogen and progesterone facilitate the development of the lesion as promoters.

LETTERS TO THE EDITORS

The Cherney incision for gynecologic cancer

To the Editors: The excellent article on the Maylard incision (Helmkamp BF, Krebs H-B. The Maylard incision in gynecologic surgery. AM J OBSTET GYNECOL 1990;163:1554-7) confirms the value of transverse incisions for gynecologic cancer surgery. I wonder whether the authors have experience with the use of the Cherney incision?

The Cherney incision involves detachment of the rectus abdominus tendon near its insertion on the pubic symphysis. Compared with the Maylard incision, it is much faster to perform, an average of 1 to 2 minutes versus 5 to 10 minutes. No drains are required because there is virtually no bleeding from the tendon, thus the risk of hematoma and seroma are markedly reduced as compared with the Maylard incision. In addition, it is often possible to spare the inferior epigastric vessels, maintaining vascularity to the rectus muscles. The major disadvantage of the Cherney incision is that occasionally there is poor development of the tendon sheath, which contraindicates this incision. In addition, about 1% to 2% of patients may rupture the tendon postoperatively if it is not repaired carefully or if there is excessive postoperative tension. Nonetheless, the Cherney incision offers greater abdominal wall strength because the rectus muscles are not required to heal by fibrosis as with the Maylard incision. We have found this to be an excellent incision for radical hysterectomy and would be interested in the authors' comments. Finally, the authors refer to the Maylard incision as a "muscle-splitting" incision (e.g., McBurney) when "muscle cutting" would be more accurate.

Reply

To the Editors: I appreciate the comments regarding our article on the Maylard incision. The Cherney incision[1] was introduced in 1941 as a variation of other transverse incisions and the pros and cons of these various incisions are discussed at length by Christopherson in his excellent article.[2] I have no personal experience with this incision; I use the Maylard incision exclusively when optimal pelvic exposure is required.

I would agree with you that "muscle cutting" would more accurately describe the Maylard technique, inasmuch as the incision through the rectus muscles is perpendicular to the muscle fibers rather than parallel.

Costs and benefits of examining all placentas

To the Editors: I read with interest the article by Salafia and Vintzileos (Salafia CM, Vintzileos AM. Why all placentas should be examined by a pathologist in 1990. AM J OBSTET GYNECOL 1990;163:1282-93) in which they advocate examination of all placentas by pathologists. In calculating the cost-effectiveness of such examination, the authors made the following assumptions that I believe are faulty:

1. An average obstetrician will be successfully sued for damages of $5 million to $6 million over his or her career.

2. Examination of placentas will clear the obstetrician of malpractice charges in all such cases in which he/she is sued.

Further comments from the authors on the above assumptions would be helpful to estimate the true cost-effectiveness of examining all placentas.

Khush Mittal, MD

Department of Pathology, New York University, School of Medicine, Bellevue Hospital, 27th St. and 1st Ave., New York, NY 10016

Reply

To the Editors: We thank Dr. Mittal for his comments. We do not, however, state that the average obstetrician will be successfully sued for $5 million to $6 million, but that in many states the average "award" for medical negligence in cases of cerebral palsy is $5 million to $6 million.

We also do not state, and certainly do not believe, that examination of the placenta will clear the obstetrician of charges in all such cases in which he/she is sued. We state that given the cost per award, the generated cost (from placental examination) is worthwhile to avoid *one* case of alleged medical malpractice. In our experience, subclinical placental pathology is frequently present in cases brought to litigation and may provide data supportive of the defense.

We appreciate the opportunity to clarify these points.

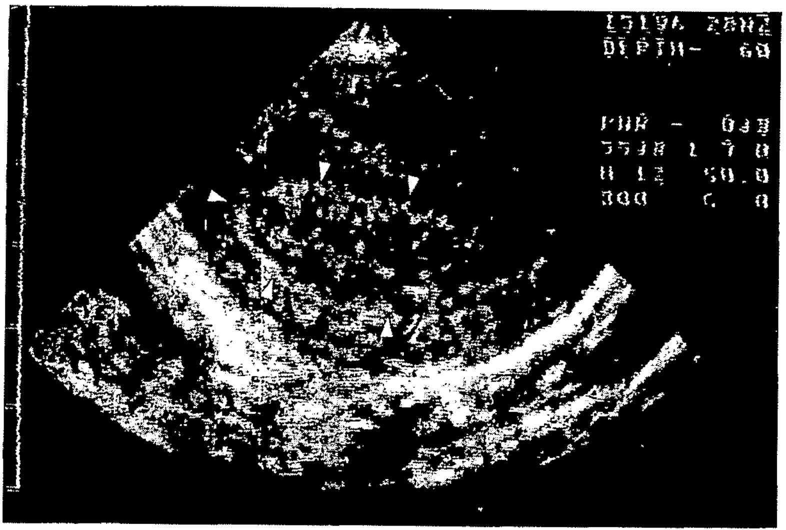

Fig. 1. This cross section of the uterus in a patient with an ectopic pregnancy shows a thick prominent decidua (outlined by *arrowheads*) that contains a few small vascular structures (2 mm anechoic areas).

Ultrasonographic visualization of endometrial vascularity with ectopic pregnancy

To the Editors: We wish to report to you and your readers that some patients with ectopic pregnancy may demonstrate endometrial vascularity on ultrasonographic examination. This is associated with a thick, prominent endometrium without other intrauterine findings of pregnancy.*

Most patients had widespread findings in the inner portion of the endometrium (decidua), which was generally hypoechoic compared with the more hyperechoic outer portion of the endometrium.[1] Sometimes we were able to show discrete vascular channels up to 2 mm in diameter (Fig. 1) with rapid or tumbling flow, whereas in other patients the flow was less well contained and appeared as scattered pulsatile-like foci or sluggish flow without discrete identifiable vessels. We propose that these observations are a result of vascular alterations known to occur in the decidua of pregnant patients. We believe these findings are most likely a result of venous structures, although it is possible that some of the pulsatile-like findings are arterial in origin.

This finding of endometrial vascularity is not specific for ectopic pregnancy. We have seen this, on occasion, with incomplete abortions with microscopic villi, complete abortions with retained decidua, in one intrauterine pregnancy, before visualization of the gestational sac and, probably pulsatile-like flow (without discrete vessels) in one nongravid patient.

Of interest, a cross section or oblique section of a vessel(s) may produce one or more hypoechoic or anechoic areas within the endometrium. This could be confused with an early intrauterine pregnancy, an abnormal intrauterine pregnancy, an early molar pregnancy, a pseudogestational sac, an endometrial cyst, a polyp with cystic degeneration, cystic endometrial hyperplasia, or less common types of endometrial pathology. This pitfall may be avoided if blood flow is seen through the vessel(s) or if a more ideal scan plan shows a clearly defined vascular structure(s).

Many questions remain unanswered (e.g., Is the visualization of endometrial vessels specific for pregnancy?) and further research needs to be performed. We would be interested in hearing the findings other investigators have in this regard.

High blood pressure in pregnancy

To the Editors: We believe that the National High Blood Pressure Education Program Working Group report on high blood pressure in pregnancy (AM J OBSTET GYNECOL 1990;163:1691-712) obscures an important issue through two contradictory statements. The section "Rationale for treatment" contains this advice: "... the cornerstone of obstetric management of preeclampsia is based on a decision as to whether the infant is more likely to survive in utero or in the nursery."

Relevant studies have long indicated that neonatal survival rates peak at the time of the expected date of confinement and decline as little as 1 week thereafter.[1] Accordingly, the philosophy of effecting delivery by 40 weeks' gestation both in acute and chronic hypertensive disorders has prevailed for decades in obstetric textbooks.[2,3] Because with contemporary management no tangible improvement in neonatal mortality and morbidity rates can be expected beyond week 38, the above statement encourages termination of pregnancy at "term" and certainly no later than the "expected date of confinement." However, the section "Fetal indications" pronounces a different recommendation: ". . . if the maternal condition is stable, delivery is indicated by signs of abnormal fetal function. If fetal growth and well-being remain normal, pregnancy should proceed to spontaneous labor."

Spontaneous labor normally occurs between 38 and 42 weeks' gestation. Only thereafter does the threat of postmaturity warrant intervention. Accordingly, the last mentioned recommendation invites waiting for labor until week 42.

Over our objections, some physicians in this geographic area embraced the last quoted management pattern in recent years and refrained from intervention in "mild" preeclampsia until week 42. This endeavor repeatedly entailed unfortunate fetal and even maternal outcomes. Consequently, whereas "severe" cases after 28 weeks' gestation almost invariably ended favorably, painful losses have resulted from conservatively treated "mild" preeclampsia.

We are familiar with the writings of various members of the Working Group and perceive the earlier cited inconsistent viewpoints as an unsuccessful attempt at reconciling two incompatible approaches to management. As a result, the report, in our opinion, fails to clarify the appropriate treatment for mild preeclampsia. With regard to its impact on perinatal statistics, this omission may offset the benefits of this prodigious work insofar as mild cases occur far more often than do severe ones. In terms of absolute numbers, we probably encountered more catastrophes from mild than from severe preeclampsia in the recent past. We fear therefore that a narrow interpretation by obstetricians of the instruction in "Fetal indications" section may lead to a similar experience nationwide.

Maternal hemodynamics in pregnancy

To the Editors: Ikeda and Mori (Ikeda T, Mori N. Assessment of cerebral hemodynamics in pregnant women by internal carotid artery pulsed Doppler velocimetry. AM J OBSTET GYNECOL 1990;163:494-8) state that to date no studies have been done of serial changes in maternal cerebral hemodynamics during pregnancy. Obviously the authors were not aware that we have examined the carotid artery, femoral artery and vein, and uterine vessels serially and longitudinally during pregnancy by Doppler ultrasonography.[1] For the carotid artery we also noticed a significant decrease of peak systolic and end-diastolic flow velocities as well as a decrease in mean velocity that was, however, not significant.

Reply

To the Editors: Drs. Baumann and Huch measured velocity in the common carotid artery. This artery divides into internal and external carotid arteries. The external carotid artery supplies blood to extracranial organs and the internal carotid artery feeds the brain. Blood flow velocity waveforms in the common carotid artery combine a high-resistant flow in the external and a low-resistant flow in the internal carotid artery.[1] When cerebral blood flow assessed by xenon 133 inhalation technique was compared with the velocity in the carotid artery measured with Doppler technique, the correlation coefficient between mean hemispheric cerebral blood flow and internal carotid end-diastolic velocity was 0.83 in the left side and 0.88 in the right side; that of common carotid artery velocity and mean hemispheric cerebral blood flow was 0.69 in the left side and 0.71 in the right side.[2] It is apparent that common carotid artery velocimetry is less specific in the assessment of cerebral blood flow.

Epidemiology of preeclampsia and eclampsia

To the Editors: We read the article by Saftlas et al. (Saftlas AF, Olson DR, Franks AL, Atrash HK, Pokras R. Epidemiology of preeclampsia and eclampsia in the United States, 1979-1986. AM J OBSTET GYNECOL 1990;163:460-5) with great interest and share the concern about the apparent steady trend of increasing rates between 1983 and 1986. Whereas diagnosis-related groups may indeed have prompted more accurate reporting and even overdiagnosing, we have found that reliance on discharge diagnoses at our institution with the use of *International Classification of Diseases, Injuries, and Causes of Death,* 9th revision (ICD 9) categories, as was done in this study, is enormously problematic for studies of hypertensive disorders in pregnancy.[1] First, fully 25% of the cases generated by ICD 9 codes at our institution proved to be incorrect diagnoses and were excluded after review of the hospital records. Second, review of all hospital records documented that 53.3% of all true cases had been missed by the coders at our insitution.

Given this, we wonder what Saftlas et al. may have done to verify the diagnoses in the National Hospital Discharge Survey data base and to check on the completeness of ascertainment. Clearly this presents a formidable task, but it is nevertheless crucial. Our data suggest that the national rates of preeclamspia and eclampsia may well be at least twice that reported in this article.

REFERENCE

1. Ales KL, Charlson ME. In search of the true inception cohort. J Chron Dis 1987;40:881-5.

Reply

To the Editors: We thank Drs. Ales and Charlson for their interest in our article. We are not suprised that the national rate of preeclampsia (2.6%) is lower than that found at individual hospitals such as The New York Hospital because such hospitals serve as major referral centers for high-risk pregnancies. Moreover, because of the demographic makeup of the obstetric population at The New York Hospital, the rates of obstetric conditions in this population almost certainly differ from the rates observed in the general obstetric population of the United States.

We agree with Drs. Ales and Charlson that the sensitivity and specificity of discharge diagnoses are not perfect. We were unable, however, to review the medical records included in our study; to preserve the confidentiality of the participating hospitals, the National Hospital Discharge Survey does not permit outside reviews. We have, however, had the opportunity to verify discharge diagnoses of preeclampsia from a population-based study we are conducting among Navajo Indian women. When we reviewed medical records from the five hospitals in the study, we found that we had underestimated the incidence by 25% when we had used hospital discharge diagnoses as our data source.

In the validation study by Ales and Charlson,[1] the accuracy of all hypertension complicating pregnancy was assessed, not just preeclampsia. Clearly, the validity of hospital discharge diagnoses can be expected to vary depending on the disease conditions under study.[2] Our review of their article indicates that at their institution, the rate of all hypertension complicating pregnancy based on hospital discharge diagnoses (7.5%) was underestimated by 57%. Thus it is not clear to us why Drs. Ales and Charlson believe that the national rate of preeclampsia was underestimated at least 100% when their data do not indicate this. Even if the national rate of preeclampsia had been underestimated by as much as 57%, the adjusted rate would be only 4.1%, a rate much lower than those reported by most hospital-based studies.

The rates of preeclampsia and eclampsia estimated from the National Hospital Discharge Survey are the only nationally representative rates published to date. Although these may underestimate the true incidence, we do not believe that the underestimate is as high as 100%. These data can be used to track trends over time and compare rates across geographic areas, but because they are population-based they should not be expected to compare to rates derived from large referral medical centers.

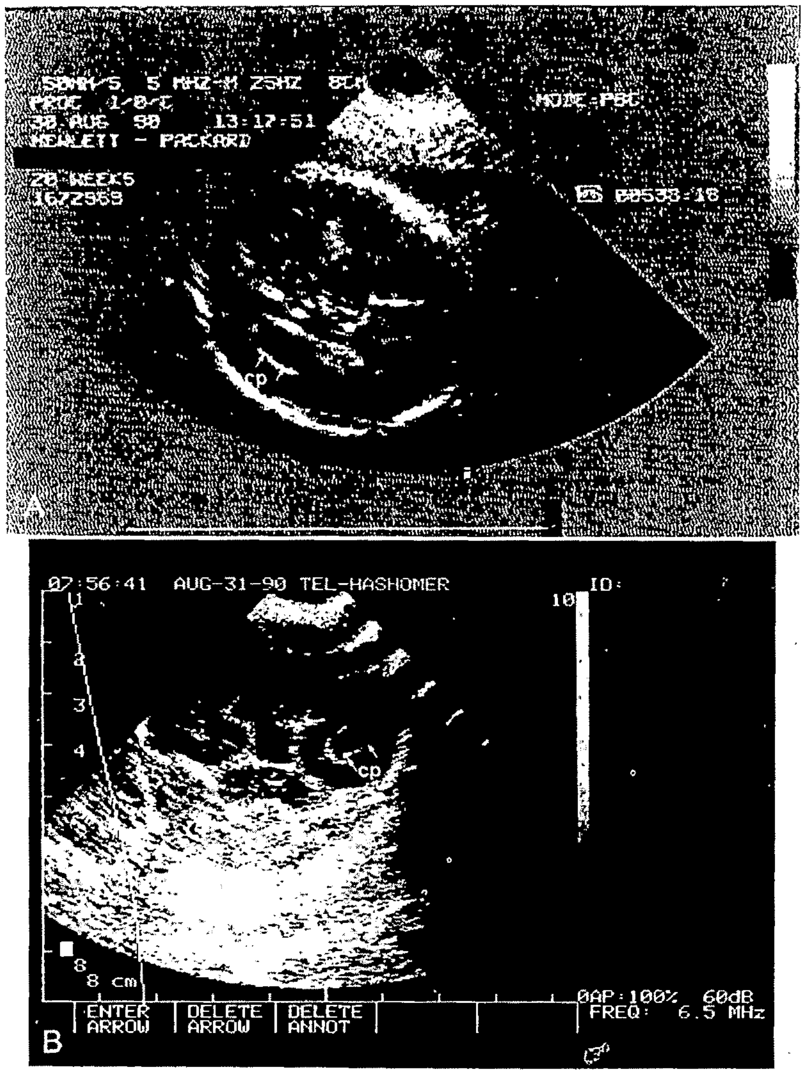

Fig. 1. A, Axial in utero scan shows small choroid plexus cyst at 19 weeks' gestation in a fetus with trisomy 18. **B,** Postabortion frontal scan (6.5 MHz) shows the same ultrasonographic appearance as in utero.

Are choroid plexus cysts an indication for second-trimester amniocentesis?

To the Editors: Drs. Benacerraf, Harlow, and Frigoletto evaluated the risk of trisomy 18 in fetuses with choroid plexus cysts of the lateral ventricle (Benacerraf BR, Harlow B, Frigoletto FD. Are choroid plexus cysts an indication for second-trimester amniocentesis? AM J OBSTET GYNECOL 1990;162:1001-6). The authors used statistical analysis to hypothesize that the risk of trisomy 18 is one for every 477 normal fetuses with choroid plexus cysts and their recommendation was to avoid amniocentesis, which has a risk of 1:200. We would like to argue with these findings and conclusions.

To evaluate the significance of choroid plexus cysts in the general population, the authors averaged the prevalence of choroid plexus cysts found in four studies (0.18%, 0.65%, 0.80%, 2.5%[1-4]), which resulted in 1%, an estimation found to be in agreement with their experience. However, the highest rate of 2.5% is not a representative figure because the study by Chan et al.[4] was performed on a small series of 513 women at level II ultrasonographic examination, resulting in a biased overestimated rate. Therefore this rate should be omitted from calculation. A large prospective study performed by us on 5400 low-risk women revealed a 0.6% rate of fetal choroid plexus cysts.[5] The addition of these 5400 cases to the other four large studies[1-3, 6] results in a total of 28,292 fetuses screened at midtrimester with an average 0.7% prevalence of choroid plexus cysts. Therefore it seems more appropriate to use 0.7% rather than the estimated 1% rate.

Furthermore, in their analysis the authors reviewed

26 fetuses with trisomy 18 and found 30% choroid plexus cysts in these cases. These 26 cases were divided into two groups: 13 fetuses with trisomy 18 who were first seen for amniocentesis (group I, Table I) and 13 fetuses with trisomy 18 who did not present with amniocentesis but were referred to them (group II, Table II). The prevalence of choroid plexus cysts in the first group was 5/13 (38%), whereas the prevalence in the second group was one of eight cases at midtrimester (12%), which has a significant statistical difference ($\chi^2 = 4.5$; $p < 0.01$). This is surprising because we would expect that in the referral patients, which is a selected group, there would be more affected cases. A possible explanation for this difference might be the sonographers' unawareness of the problematic issue of fetal choroid plexus cysts because the first publication on this subject by Chudlight et al.[6] appeared in 1984, whereas their study commenced on Jan. 1, 1983.

Moreover the 30% prevalence of choroid plexus cysts in trisomy 18 found by Benacerraf et al. seems lower in comparison with the interesting ultrasonographic study performed by Fitzsimmons et al.[7] They found among 14 aborted fetuses with trisomy 18, 71% (5/7) had choroid plexus cysts at midtrimester. Benacerraf et al. claimed that the high rate obtained by Fitzsimmons et al. was a result of the in vitro study, which enabled better resolution of the lesions. We do not agree with this speculation because we compared the in vivo and in vitro appearance of choroid plexus cysts and obtained the same size and lesion shape prenatally and postnatally (Fig. 1, *A* and *B*).

Although it is clear that choroid plexus cysts can occur in fetuses with trisomy 18, the risk of such a chromosomal abnormality in a fetus with an incidental finding of choroid plexus cysts is difficult to determine. Because trisomy 18 is an uncommon disease that occurs three per 10,000 births, a large prospective study is needed to resolve this problem. While awaiting such a definitive study, the question of how to manage such pregnancies remains. Indirect estimation on the basis of published data may be of value. We reviewed the literature and collected data only on fetuses at midtrimester (15 to 24 weeks' gestation) with trisomy 18 and choroid plexus cysts; sporadic case reports were excluded. A total of 33 cases with midtrimester diagnosis of trisomy 18 were cumulated; among them were 18 (55%) fetuses with choroid plexus cysts. Thus we can conclude that the known prevalence of choroid plexus cysts in trisomy 18 is about 55%.

With these figures in mind we can proceed with the authors' hypothesis that for 33 cases with trisomy 18 a hypothetical sample of 110,000 women is needed. With a 0.7% prevalence of choroid plexus cysts, 770 normal cases with this abnormality would be detected. It is known that 30% of these cases have no other detectable anomalies on ultrasonography. Multiplication of 30% per 18 cases results in a product of 5.4 fetuses with trisomy 18 with choroid plexus cysts and without other findings, or one fetus with trisomy 18 for every 142 (770/5.4) normal fetuses with choroid plexus cysts. This is higher than a 35-year-old woman's risk of having a child with trisomy 21, which is 0.27%, a widely accepted threshold for consideration of amniocentesis. We therefore suggest that until a larger prospective study determines the real risk of trisomy 18 in the fetus with choroid plexus cysts, amniocentesis is warranted.

Reply

To the Editors: We appreciate the interest in our work shown by this letter; however, we do not agree with the conclusions reached concerning either the prevalence of choroid plexus cysts in the general population or the prevalence of choroid plexus cysts in fetuses with trisomy 18. We averaged the prevalence of choroid plexus cysts in the four studies cited because these were indeed the largest studies of their kind available. I see no reason to omit either the highest or the lowest prevalence among these four and certainly cannot include the authors' series, which has yet to be published in a peer-reviewed journal. Therefore in our opinion the best estimate of choroid plexus cysts in the general fetal population in the mid phase of the second trimester is 1%, which seems to be in keeping with our experience.

The authors of the letter question the prevalence of choroid plexus cysts in the first group versus the second group of fetuses with trisomy 18 in our article. The difference in prevalence may be a result of the second group being strictly referrals for fetal anomalies, whereas patients in the first group were undergoing amniocentesis for advanced maternal age and therefore were a different subpopulation. The prevalence of choroid plexus cysts suggested by Fitzsimmons et al., however, is still thought to be an overestimate because they used higher frequency transducers, which are known to have better resolution than those used for in vivo obstetric ultrasonography. Even though the authors of the letter show one case of a large choroid plexus cyst seen both in vitro and in vivo, this does not in any way demonstrate the difference in the identification of smaller choroid plexus cysts that may not be quite as obvious. The prevalence of a small structure seen in vitro with higher resolution transducers cannot be applied to an in vivo experience unless a proper control study is included.

Furthermore, the authors of the letter have come up with a prevalence of choroid plexus cysts of 55% among fetuses with trisomy 18. There is absolutely no basis for this number because they have gathered cases of trisomy 18 at random in the literature, most of which are being reported because of the presence of choroid plexus cysts. Therefore the denominator of all the fetuses with trisomy 18 coming from all these different laboratories is totally unknown and the prevalence of choroid plexus cysts among fetuses with trisomy 18 in this heterogeneous population is irrelevant.

In the last paragraph of the letter, the authors claim that 30% of our cases with trisomy 18 had no other abnormalities on ultrasonography. This shows a misreading of our manuscript because there were 6 of 26, or 23%, with no other abnormalities.

In conclusion, a large prospective study would be most helpful to determine the risk of a fetus to have trisomy 18 when choroid plexus cysts are present without any other ultrasonographic abnormalities. In the absence of such a study, statistical analysis can be used to estimate this risk, as we have shown in our article. We have used the most accurate incidences for choroid plexus cysts in the general population available in the literature and believe that to date there is no reason to revise these numbers.

Reproductive Scientist Training Program. The Reproductive Scientist Training Program is designed to facilitate the basic research training and career development of obstetrician-gynecologists and to further investigation in the reproductive sciences in medical school departments of obstetrics and gynecology. The areas of research covered by the program are broadly defined, but the emphasis is on cell and molecular biology as applied to problems in reproductive endocrinology, genetics, maternal-fetal medicine, oncology, infectious disease, or other aspects of reproduction. Specifically, we wish to attract promising physicians in their fourth year of obstetric/gynecologic residency or near completion of a subspecialty fellowship who desire, in addition to their clinical skills, to develop strong basic science research skills and understanding in fields such as cell and molecular endocrinology, molecular genetics, molecular immunology, and molecular oncology as related to reproductive medicine. This program will consist of 2 or 3 years of basic research training after completion of a residency in obstetrics and gynecology or subspecialty fellowship. These initial 2 or 3 years of laboratory investigation will be followed by a 3-year period in a department of obstetrics and gynecology, during which time the individual will be expected to spend at least 75% time in research, with the balance for clinical activity. Thus the complete program entails a 5- to 6-year commitment to basic scientific investigation. This research training program is sponsored by the American College of Obstetricians and Gynecologists, American Fertility Society, American Gynecological and Obstetrical Society/American Association of Obstetricians and Gynecologists Foundation, Association of Professors of Gynecology and Obstetrics, APGO Medical Education Foundation, Council on Resident Education in Obstetrics and Gynecology, GynoPharma Incorporated, Johnson and Johnson Medical Incorporated, and the National Institute of Child Health and Human Development. We wish to attract promising physicians who will have completed an approved 4-year residency program and who desire to spend several years developing strong basic science research skills in addition to their clinical skills, and who are committed to a career in academic obstetrics and gynecology. Women and minorities are encouraged to apply. For more information please write: Executive Director, Association of Professors of Gynecology and Obstetrics, 409 12th St., S.W., Washington, DC 20024. Deadline for applications is October 15, 1991, to start July 1, 1992.

Modern medicine's answer to normal memory loss.

A lively and authoritative review of the year's best journal literature.

Let's face it. Remembering everything from the hundreds of articles you read is a herculean task. You're bound to forget a few important details. It's normal. It's healthy. But with a subscription to the *Year Book of Obstetrics and Gynecology*, it's also unnecessary.

Each year, the *Year Book of Obstetrics and Gynecology* brings you the most important articles relating to obstetrics and gynecology. The articles, chosen by our distinguished editors, are abstracted into concise one and two page summaries for quick and efficient reading. Nearly every article is accompanied by personal commentary from the editors discussing its significance to your daily practice.

The *Year Book of Obstetrics and Gynecology*— it's the best way to remember what you shouldn't forget.

☐ **Yes! I want an overview of the year's most important journal literature.**

Please send my 30-day FREE examination copy of the *1991 Year Book of Obstetrics and Gynecology* (22118) by Daniel R. Mishell, Jr. If I decide to keep the book I'll pay $57.95 plus shipping and handling.

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

Each bimonthly issue focuses on a specific clinical problem you see in your practice *or* on a subject area in which important clinical and research information is being generated. Particular emphasis is devoted to the management of fertility and other endocrine problems, as well as high-risk obstetrics.

In one convenient resource, you'll have a complete and up-to-date analysis of such topics as:

- Preconceptual counseling
- Labor in the primigravid patient
- Diagnosis and treatment of primary and secondary amenorrhea
- Pediatric and adolescent gynecology

You get up-to-date information too urgent to await book publication, yet too important to be summarized in a brief journal article. Authors for each issue are selected for their expertise; you'll benefit from their wealth of clinical experience and their balanced perspective on the topic.

In addition, each article is extensively referenced, allowing you to easily locate additional information on related topics. For a quick overview, each article includes an abstract and an "In Brief" section covering the major points in the article.

Current Problems in Obstetrics, Gynecology and Fertility will help to keep you at the forefront of your specialty. Subscribe today by calling our toll-free number or by returning the coupon below.

ETSU is an AA/EOE

CHAIR, DEPARTMENT OF OB-GYN

An 830-bed regional tertiary care teaching hospital is seeking a Chair for its Department of OB-GYN. The Allentown Hospital–Lehigh Valley Hospital Center has a fully-approved, free-standing OB-GYN Residency Program with two residents each year and trains a total of 70 residents and 400 medical students.

The hospital is a regional Level III Perinatal Center. Of over 3,000 births in 1990, 42 percent were in the high-risk category. The department is supported by a 20-bed Level III NICU managed by four full-time neonatologists.

In response to the continuing growth of the community and the expansion of the OB-GYN Department, the hospital will ask the new Chair to lead the search for the newly-created position of Vice Chair/Program Director of OB-GYN. The department is also awaiting the arrival of the new Chair to help in the search for a full-time perinatologist. (There are 33 active OB-GYN physicians on staff, including a gynecologic oncologist and reproductive endocrinologist.)

The hospital is a clinical campus of Hahnemann University in Philadelphia, where the new Chair will hold a Vice Chair appointment and an academic appointment at the rank of associate or full professor. The hospital is in Allentown, a burgeoning area in eastern Pennsylvania within close proximity of Philadelphia and New York City.

Candidates must be board certified with administrative experience and familiarity with both academic and community hospital environments. Interested candidates may write or call for information and send curricula vitae, in confidence, to: **Headley S. White, Jr., M.D., Sr. Vice President, Medical and Academic Affairs, c/o HealthSearch, 1243 S. Cedar Crest Blvd., Suite 3000, Allentown, PA 18103, (215) 821-3090.** Descriptive brochure available.

LAUREL, MISSISSIPPI

Join two-physician group or one physician in association. 275-bed hospital. Community of 30,000 is 90 minutes from the Gulf Coast and two hours from New Orleans, Louisiana.

Excellent financial package includes paid interviewing and relocation expenses. Send your CV or call:

PERINATOLOGIST

Outstanding practice opportunity for a BC/BE perinatologist to join an established practice at Iowa's largest private teaching medical center. The hospital, a state designated Level III Perinatal Center, averages over 2,000 deliveries annually and has an active maternal and neonatal transport system. The medical center's Level III Neonatal Intensive Care Unit is staffed by four board certified neonatologists. Complete laboratory facilities are available including cytogenic analysis of both amniotic fluid and trophoblastic tissue. The Antepartum Testing Unit is equipped with computer-based fetal monitors and a color flow Doppler ultrasound unit. Excellent financial and lifestyle opportunities are available to the qualified candidate. Please call 1-800-882-5911 or send CV to Mariann Clark, Medical Search Consultant, 1200 Pleasant Street, Des Moines, Iowa 50309.

DOOR COUNTY, WISCONSIN

BC/BE Obstetrician/Gynecologist to join established BC OB/GYN in hospital - based practice. Complete practice facilities available. New LDRP Birthing Center in modern, progressive 89 - bed community hospital. Competitive guaranteed salary and incentive package. Malpractice insurance. Attractive benefits.

Door County offers exceptional four season recreation along Lake Michigan shores, proximity to Milwaukee and Chicago, top rated schools and quality community life for family.

CHIEF, OBSTETRICS/GYNECOLOGY

Newton-Wellesley Hospital, a 340-bed Tufts affiliated community teaching hospital, located less than 10 miles west of Boston, is conducting a search for a Chief to head the Department of Obstetrics & Gynecology. This position is full-time including practice opportunities.

Candidates must be board certified in Obstetrics and Gynecology and have strong clinical interests and skills, a commitment to family-centered patient care, management skills, and an ability to lead an active educational program geared to the needs of a rapidly growing department. Interest and expertise in one of the subspecialties of Obstetrics and Gynecology is preferred.

There are currently 3600 deliveries per year at the Newton-Wellesley Hospital, with continued growth anticipated. The Maternity Facility consists of a 20-bed LDRP Unit, 6 LDR suites, 2 C-section/high risk delivery suites, 2-bed PACU and 24-bed post partum unit, and an antenatal testing unit. This service is supported by a 12-bed, Level II, special care nursery, as well as full-time neonatology and anesthesia coverage.

The successful candidate will be responsible for the ongoing clinical, administrative, and teaching activities for the department, as well as for the direction of its active growth and development.

Interested candidates should forward their curriculum vitae to: Joel Rubenstein, M.D., Chairman, Search Committee, Newton-Wellesley Hospital, 2000 Washington Street, Newton, MA 02162.

NWH is an equal opportunity employer.

Faculty Position
Maternal Fetal Medicine
Southern Illinois University School of Medicine
Springfield, Illinois

The Department of Obstetrics and Gynecology at Southern Illinois University School of Medicine, Springfield, Illinois is expanding the Division of Maternal Fetal Medicine and is seeking one new faculty at the Assistant or Associate Professor level. The division serves as a state-of-the-art perinatal referral center for central and downstate Illinois and is responsible for providing tertiary care to high risk obstetrical patients, including antenatal testing, perinatal ultrasonography (including Doppler), and fetal evaluation and therapy with planned expansion of its prenatal diagnostic services to include CVS. Division faculty are also responsible for the development of educational curriculum and delivery of instruction to medical students, residents, and fellows. The division is committed to research activities pertinent to maternal fetal medicine, and research opportunities are available. Certification or eligibility in the subspecialty is required.

Send Curriculum Vitae to: Robert D. Hilgers, M.D., Professor & Chairman, Department of OB/GYN, Southern Illinois University School of Medicine, P.O. Box 19230, Springfield, IL 62794. Phone: (217) 782-8247. Or send inquiries to Robert C. Kaufmann, M.D., Chief, Division of Maternal Fetal Medicine.
Phone: (217) 785-5540

SIU is an AA-EEO Employer

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for four (4) full-time faculty positions for a new women's health center and academic program at its Milwaukee Clinical Campus.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5500 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin and St. Luke's Medical Center in Milwaukee.

Qualifications include board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the four positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

- STATEWIDE FAMILY PLANNING AND AMBULATORY CARE (Part-time medical director, Planned Parenthood)
- OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
- UROGYNECOLOGY
- RESIDENCY/MEDICAL STUDENT EDUCATION
- OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faculty members participate in a group practice at the institution. Contact:

Chester B. Martin, M.D.
Chairman

University of Kansas School of Medicine-Wichita
HCA-Wesley Medical Center
550 N. Hillside
Wichita, KS 67214

An Affirmative Action/Equal Opportunity Employer

STAFF PERINATOLOGIST

Our **Maternal Fetal Medicine Section** is seeking to increase its current staff of six perinatologists and one geneticist, to cover our rapidly expanding responsibilities in the fields of prenatal diagnosis and high risk obstetrics.

PENNSYLVANIA HOSPITAL, the Nation's First Hospital, is a tertiary care center, located in the historic Society Hill Section of Philadelphia.

Our section provides perinatal consultation, ultrasound evaluation, and fetal testing to an extensive referral network of surrounding institutions. Pennsylvania Hospital is also the site of the International PUBS Registry, has an active prenatal diagnosis program involving CVS and amniocentesis, and a committment to teaching with four Maternal Fetal Medicine Fellows.

Faculty appointment at the **University of Pennsylvania School of Medicine** is available. Malpractice insurance coverage and a liberal benefit package are offered. All applicants must be board certified or board eligible.

For more information, please write or contact:

Stuart Weiner, M.D.
Section Chief, Maternal Fetal Medicine
Department of Obstetrics/Gynecology
Pennsylvania Hospital
800 Spruce Street
Philadelphia, PA 19107
(215) 829-5808

Pennsylvania Hospital is an affirmative equal/action opportunity employer.

DIRECTOR OF MATERNAL-FETAL MEDICINE

Albert Einstein Medical Center (AEMC), a 600+ bed tertiary care teaching hospital, is seeking a board certified maternal-fetal medicine subspecialist as Director of the Division of Maternal-Fetal Medicine to develop and direct the comprehensive perinatal program in this institution. AEMC is a major referral center in north Philadelphia supporting numerous post-graduate medical education programs, including a fully accredited residency program in obstetrics and gynecology. The Department of Obstetrics and Gynecology has a long-standing tradition of excellence in healthcare delivery and supports a variety of clinical research and educational activities. The Division of Maternal-Fetal Medicine serves as a tertiary referral center within the metropolitan Philadelphia area. Its service includes maternal intensive care unit, maternal transport program, high risk obstetrics, genetic counseling, diagnostic genetic procedures (amniocentesis, CVS, cordocentesis), targeted (level II) obstetrical ultrasound and comprehensive antenatal fetal surveillance. Our Department is supported by a Level III NICU and a Cytogenetic Laboratory. There is a strong institutional support and emphasis in research with funds and laboratory space available for basic research. A construction project is under way for a new labor and delivery suite and a comprehensive fetal diagnostic center. We are also planning to develop a maternal-fetal medicine fellowship training program with Temple University.

AEMC is a major affiliate with Temple University. Academic appointment is available for all full-time AEMC faculty. Highly competitive salary and very attractive fringe benefits are included. If you are interested in this position or would like additional information about this unique opportunity, please write to Sze-ya Yeh, M.D., Chairman, Department of Obstetrics and Gynecology, Albert Einstein Medical Center, 5401 Old York Road, Klein #410, Philadelphia, PA 19141. Telephone (215) 456-6993, FAX (215) 456-6271.

PERINATAL ASSOCIATES OF NORTHERN CALIFORNIA

Are you a clinical perinatologist? There is still time to join four perinatologists and one geneticist-OB/GYN looking for one more perinatologist who: desires superior environment for patient care, in a private, modern, level 3 facility doing 6,000 deliveries a year with superior perinatal outcome; likes personal, direct hands-on patient care; needs PUBS, IUTxF, CVS and complicated pregnancies, level 2 ultrasound; demands partners, not superiors; wants to live in clean, warm, not humid, snow-free (but 60 minutes from skiing) Sacramento, California; feels one's family has priorities, and is committed to the private practice of medicine. For more information, call (916) 733-1755, extension 2773.

Maternal Fetal Medicine Fellowship
Department of Obstetrics and Gynecology

Southern Illinois University School of Medicine
Springfield, Illinois

The Department of Obstetrics and Gynecology at Southern Illinois University School of Medicine, Springfield, Illinois has one first year Fellowship position available in Maternal Fetal Medicine beginning July 1, 1992. This is a two year accredited Fellowship program in which both clinical and research training are emphasized. Clinical material is drawn from the 3000 deliveries/year at St. John's Hospital Perinatal Center where fellows participate in a supervised, in-depth experience in management and treatment of medical and obstetrical complications with emphasis on antenatal diagnostic procedures and ultrasound techniques. This flexible program incorporates a minimum six month period of full time research and accommodates various clinical/research objectives based on the fellow's individual goals. Fellows are encouraged to present papers and to represent the Maternal Fetal Medicine Division at national scientific meetings.

ORTHO-NOVUM® 7/7/7 Tablets

norethindrone/ethinyl estradiol

Low incidence of androgenic side effects

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.
CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

ORTHO

Outstanding Clinical Performance Reflected Inside & Outside

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM* 7/7/7 patients†: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.‡[1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.§

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

Low incidence of androgenic side effects

21- and 28-day regimens

ORTHO-NOVUM 7/7/7 Tablets

TRADEMARK

norethindrone/ethinyl estradiol

---

*Trademark

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

‡Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

§An increase in blood pressure has been reported in women taking oral contraceptives.

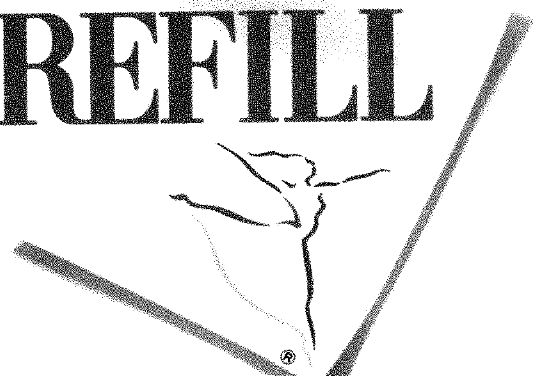
FEMSTAT® PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%



SYNTEX
SYNTEX LABORATORIES INC
PALO ALTO CA 94304

Committed to the OB/GYN and women's healthcare

FEMSTAT PREFILL
(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

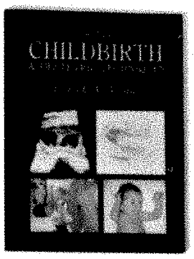
YOUR PATIENTS COUNT ON YOU FOR ANSWERS...

Here are two "must-have" resources to help you explain the mysteries of childbirth to your patients. Using dramatic full-color photos and ultrasound scans, these atlases provide step-by-step coverage of fetal development and childbirth.



New!

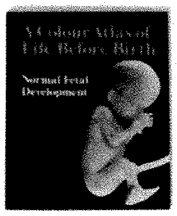
A COLOR ATLAS OF CHILDBIRTH AND OBSTETRIC TECHNIQUES
Farook Al-Azzawi, MBChB, MA, PhD, MRCOG

- Includes coverage of breech delivery, management of twins, operative vaginal delivery and the three most common types of caesarean births.
- Full color photographs depict all aspects of childbirth, with line drawings used to explain movement of the baby.
- Covers prenatal care and management of labor.

1991. 144 pages, 341 ills. A Wolfe Medical Publishers, Ltd. title. (Book Code: 06287)

New!

COLOR ATLAS OF LIFE BEFORE BIRTH: Normal Fetal Development
Marjorie A. England



- Section I covers overall development of the embryo and fetus and their relationship to the placenta, amnion and chorionic sac.
- Section II provides extensive details on the development of individual organ systems.

1990. 216 pages, 716 ills. with 710 in color. A Wolfe Medical Publishers, Ltd. title. (Book Code: 20326)

THE GOOD THINGS SHE DOES FOR HERSELF, SHE STAYS WITH…

She stays with TRIPHASIL®
for the same reasons
she started with it:

- Minimal breakthrough bleeding from Day 1
- Low estrogen dose
- Low incidence of common OC side effects*

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

Worldwide Leadership in Female Healthcare

WYETH-AYERST LABORATORIES
Philadelphia, PA 19101

© 1991, Wyeth-Ayerst Laboratories.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. See prescribing information.

See brief summary on adjacent page.

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG: free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days. For full details on dosage and administration see prescribing information in package insert.

TRANSACTIONS OF THE FIFTY-THIRD ANNUAL MEETING OF THE SOUTH ATLANTIC ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Our shield: Competence with compassion 243
M. Tucker Laffitte, Jr., MD
Columbia, South Carolina

Characterization of in vitro chemosensitivity of perioperative human ovarian malignancies by adenosine triphosphate chemosensitivity assay 245
Robert T. Gerhardt, MPH, James P. Perras, PhD, Bernd-Uwe Sevin, MD, PhD, Edgar Petru, MD, Reinaldo Ramos, BS, Lucy Guerra, and Hervy E. Averette, MD
Miami, Florida

Adenosine triphosphate bioluminescence is an efficient and reliable technique for characterizing chemosensitivity of human tumors in vitro, bearing results consistent with clinical response reports in the literature.

Single-center comparison of results of 1000 prenatal diagnoses with chorionic villus sampling and 1000 diagnoses with amniocentesis 255
S. Robert Young, PhD, Charles F. Shipley, MD, Ronald V. Wade, MD, Janice G. Edwards, MS, Marsha B. Waters, BS, Mona L. Cantu, BS, Robert G. Best, PhD, and Edward J. Dennis, MD,
Columbia, South Carolina

Chorionic villus sampling appears to be a safe and accurate alternative to amniocentesis for the purpose of genetic prenatal diagnosis at regional centers.

Quantification of cervical change: Relationship to preterm delivery in the multifetal gestation 264

Roger B. Newman, MD, Raleigh K. Godsey, MD, Janna M. Ellings, RN, CNM, Berry A. Campbell, MD, Daniel P. Eller, MD, and M. Clinton Miller III, PhD
Charleston, South Carolina

Predictive information regarding the risk of preterm delivery in multifetal gestations is provided by the antepartum cervical examination expressed as a quantifiable cervical score.

Appropriateness of intrapartum fetal heart rate management and risk of cerebral palsy 272

Paula J. Melone, DO, J.M. Ernest, MD, Michael D. O'Shea, Jr., MD, and Kurt L. Klinepeter, MD
Winston-Salem, North Carolina

There is no difference in frequency of inappropriate intrapartum fetal heart rate management during labor as compared between infants with cerebral palsy and normal infants.

Resolution of chronic pelvic pain after laparoscopic lysis of adhesions 278

John F. Steege, MD, and Anna L. Stout, PhD
Durham, North Carolina

Behavioral and psychologic variables are the best predictors of response to laparoscopic lysis of adhesions for treatment of chronic pelvic pain.

Combined interferon alfa and doxorubicin in the treatment of advanced cervical cancer 284

Charles E. Welander, MD, Howard D. Homesley, MD, and Rolland J. Barrett, MD
Winston-Salem, North Carolina

On the basis of preclinical data interferon alfa and doxorubicin were used to treat patients with advanced cervical cancer; responses were seen in 6 of 17 evaluable patients.

CEFOTAN® IM/IV

(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT.)

INDICATIONS AND USAGE

Treatment: CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis*, and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), *E coli*, *Proteus mirabilis*, and *Serratia marcescens*.*

Skin and Skin Structure Infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*, *Streptococcus pyogenes*, *Streptococcus* species (excluding enterococci), *E coli*, *Klebsiella pneumoniae*, and *Peptococcus** and *Peptostreptococcus* sp.*

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*, *Streptococcus* species (excluding enterococci), group B streptococci, *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, and *B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species).

Intra-abdominal Infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B distasonis*, *B ovatus*, and *B thetaiotaomicron*), and *Clostridium* species.*

Bone and Joint Infections caused by *Staphylococcus aureus*.*

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

Note: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Prophylaxis: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Usage in Pregnancy: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Usage in Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

During postmarketing experience with CEFOTAN, agranulocytosis, anaphylactic reactions, fever, hemolytic anemia, leukopenia, prolonged prothrombin time with or without bleeding, pseudomembranous colitis, and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION

Treatment: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

Prophylaxis: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

Impaired Renal Function: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:}\quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:}\quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

Primary invasive vaginal carcinoma 292
Gary L. Eddy, MD, Richard D. Marks, Jr., MD, M. Clinton Miller III, PhD, and
Paul B. Underwood, Jr., MD
Charleston, South Carolina

Lower stage, younger age, and absence of symptoms at detection were statistically significant favorable prognostic factors in 91 patients with vaginal cancer.

Analysis of 500 obstetric and gynecologic malpractice claims: Causes and prevention 298
Charles J. Ward, MD
Atlanta, Georgia

Five hundred obstetric and gynecologic malpractice litigation claims were analyzed to determine their causes and to find ways to prevent future claims.

Changes in lipids and lipoproteins with long-term estrogen deficiency and hormone replacement therapy 307
R. Don Gambrell, Jr., MD, and Ana-Zully Teran, MD
Augusta, Georgia

Progestogens, and even androgens, do not adversely affect lipids and lipoproteins over the long term when adequate dosages of estrogens are given to postmenopausal women.

Endometrial morphology in asymptomatic postmenopausal women 317
David F. Archer, MD, Kathleen McIntyre-Seltman, MD, Walter W. Wilborn, Jr., PhD,
Edmond A. Dowling, MD, Frederick Cone, BS, George W. Creasy, MD, and
Michael E. Kafrissen, MD, MPH
Pittsburgh, Pennsylvania, Mobile, Alabama, and Raritan, New Jersey

A low incidence (1/1000 to 2/1000) of abnormal endometrial morphologic characteristics was present in a population of asymptomatic postmenopausal women.

Assessment of Kegel pelvic muscle exercise performance after brief verbal instruction 322
Richard C. Bump, MD, W. Glenn Hurt, MD, J. Andrew Fantl, MD, and Jean F. Wyman, PhD
Richmond, Virginia

Twenty-three of 47 women generated an ideally effective Kegel contraction after brief verbal instruction; clinical and urodynamic parameters did not predict success.

Vulvar squamous cell carcinoma and papillomaviruses: Two separate entities? 329
Willie A. Andersen, MD, Douglas W. Franquemont, MD, John Williams, Peyton T. Taylor, MD, and
Christopher P. Crum, MD
Charlottesville, Virginia

Invasive squamous cell carcinoma of the vulva, unlike vulvar intraepithelial neoplasia, is only infrequently associated with human papillomavirus deoxyribonucleic acid.

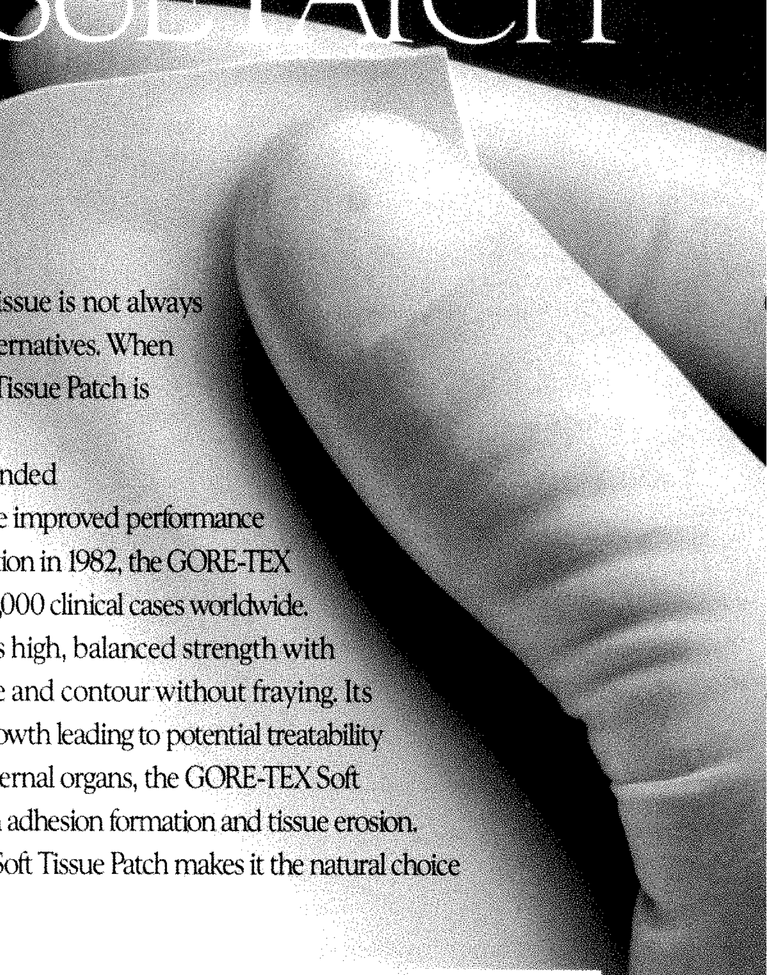
THE NATURAL CHOICE

GORE-TEX® SOFT TISSUE PATCH



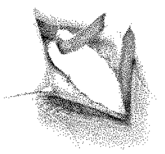
In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

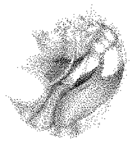
This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions





☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

Treatment failure of genital condylomata acuminata in women: Role of the male sexual partner 337
Hans-B. Krebs, MD, and B. Frederick Helmkamp, MD
Richmond and Falls Church, Virginia

Treatment of the male sexual partner does not appear to decrease the treatment failure rate of condylomata acuminata in women.

Partial dissection of the zona pellucida of frozen-thawed human embryos may enhance blastocyst hatching, implantation, and pregnancy rates 341
Michael J. Tucker, PhD, Jacques Cohen, PhD, Joe B. Massey, MD, Mary P. Mayer, RNC, Sharon R. Wiker, BS, and Graham Wright, BSc
Atlanta, Georgia, and New York, New York

Changes in the zona pellucida during freezing may ultimately restrict blastocyst hatching of the thawed embryo; this may be remedied by zona dissection before uterine transfer.

CLINICAL SECTION

■ Clinical Opinion

Polycystic ovary syndrome and the androgen-insulin connection 346
Shahla Nader, MD
Houston, Texas

A unified concept of polycystic ovary syndrome and its androgen-insulin connection that incorporates a role for hyperinsulinemia in the androgen excess observed (and vice versa) is proposed.

Ultrasonographic screening for the Down syndrome fetus 349
Charles J. Lockwood, MD, Lauren Lynch, MD, and Richard L. Berkowitz, MD
New York, New York

The value of second-trimester ultrasonography in the detection of Down syndrome fetuses appears limited by both biologic and technical constraints.

■ Clinical Articles

The fetal-pelvic index: A method of identifying fetal-pelvic disproportion in women attempting vaginal birth after previous cesarean delivery 353
Gary R. Thurnau, MD, David H. Scates, MD, and Mark A. Morgan, MD
Oklahoma City, Oklahoma

The fetal-pelvic index is an accurate method of identifying the presence or absence of fetal-pelvic disproportion in women attempting vaginal birth after previous cesarean delivery.

Acute myocardial infarction associated with prostaglandin E_2 359
William J. Meyer, MD, Steven L. Benton, MD, Timothy J. Hoon, PharmD, Daniel W. Gauthier, MD, and Valerie E. Whiteman, MD
Chicago, Illinois

Prostaglandin E_2 was associated with an acute myocardial infarction in a patient with severe hypertension undergoing therapeutic termination of pregnancy.

CA 125 regression: A model for epithelial ovarian cancer response 360
Richard E. Buller, MD, PhD, Michael L. Berman, MD, Jeffrey D. Bloss, MD, Alberto Manetta, MD, and Philip J. DiSaia, MD
Orange, California, and Iowa City, Iowa

The rate of decline of CA 125 in patients with effective treatment of ovarian cancer is described by an exponential regression curve.

Uterine rupture at term pregnancy with the use of intracervical prostaglandin E_2 gel for induction of labor 368
Ron Maymon, MD, Adrian Shulman, MD, Meir Pomeranz, MD, Michael Holtzinger, MD, Luis Haimovich, MD, and Charles Bahary, MD
Kfar Saba, Israel

Uterine rupture at term pregnancy after cervical application of prostaglandin E_2 gel is reported.

External cephalic version after previous cesarean section 370
Bruce L. Flamm, MD, Marc W. Fried, MD, Neal M. Lonky, MD, and Wendy Saurenman Giles, MD
Los Angeles, Riverside, and Anaheim, California

External cephalic version was successful in 82% of attempts, and 65% of these patients went on to vaginal deliveries.

One-blade rotation of a persistent posterior vertex 373
Jorge O. Escamilla, MD, and Stephen J. Carlan, MD
Brooksville, Florida

A technique useful in rotating malpositioned heads by use of a single forceps blade is described.

Comparative efficacy of clindamycin versus erythromycin in eradication of antenatal *Chlamydia trachomatis* 375
Lindsay S. Alger, MD, and Judith C. Lovchik, PhD
Baltimore, Maryland

Oral clindamycin is an effective and well-tolerated alternative to standard erythromycin regimens for the treatment of antenatal *Chlamydia trachomatis* infection.

Contents

Enhanced sensitization after cordocentesis in a rhesus-isoimmunized pregnancy 382

Scott N. MacGregor, DO, Richard K. Silver, MD, and John S. Sholl, MD
Evanston, Illinois

Enhanced sensitization may occur after cordocentesis in rhesus-isoimmunized pregnancy and should be considered in the management of these pregnancies.

Congenital hydronephrosis: Correlation of fetal ultrasonographic findings with infant outcome 384

Jane E. Corteville, MD, Diana L. Gray, MD, and James P. Crane, MD
St. Louis, Missouri

Ultrasonographic findings are correlated with postnatal outcome in 63 fetuses with dilated renal pelves to establish appropriate guidelines for prenatal diagnosis of congenital hydronephrosis.

Endomyocardial ultrastructural findings in preeclampsia 389

John R. Barton, MD, Adam K. Hiett, MD, William N. O'Connor, MD, Steven E. Nissen, MD, and John W. Greene, Jr., MD
Lexington, Kentucky

Endomyocardial biopsy specimens from a patient with severe preeclampsia revealed extensive endothelial and mitochondrial injury on ultrastructural examination.

High risk of human papillomavirus infection and cervical squamous intraepithelial lesions among women with symptomatic human immunodeficiency virus infection 392

Sten H. Vermund, MD, PhD, Karen F. Kelley, MPH, Robert S. Klein, MD, Anat R. Feingold, MD, MPH, Klaus Schreiber, MD, Gary Munk, PhD, and Robert D. Burk, MD
Bronx, New York

Symptomatic human immunodeficiency virus–infected women have the highest risk of human papillomavirus infection and associated cervical squamous intraepithelial lesions.

Case report of laparoscopic cholecystectomy in the third trimester of pregnancy 401

Rita O. Pucci, MD, and Randolph W. Seed, MD, PhD
Chicago, Illinois

The first reported case of laparoscopic cholecystectomy in the third trimester of pregnancy and a discussion of maternal-fetal benefits of this procedure compared with open cholecystectomy are reviewed.

Psychosocial support for maternal stress during pregnancy: Effect on birth weight 403

Alan D. Rothberg, MB, BCh, and Bernice Lits, MA
Johannesburg, South Africa

In a group of psychosocially stressed women, support during pregnancy was effective in decreasing the number of infants with birth weights <3000 gm.

(Contents continued on page 14A)

Contents

Transvaginal removal of ovaries with endoloop sutures at the time of transvaginal hysterectomy 407

Mitchel S. Hoffman, MD
Tampa, Florida

The endoloop suture facilitated transvaginal oophorectomy.

Improving disclosure of smoking by pregnant women 409

Patricia Dolan Mullen, DrPH, Joseph P. Carbonari, EdD, Ellen R. Tabak, PhD, and Marianna C. Glenday, MPH
Houston, Texas

Comparison of questions to elicit true smoking status at entry into prenatal care indicates that a multiple choice question improves disclosure over the usual "yes-or-no" format, whether in oral or written form.

Thrombotic thrombocytopenic purpura first seen as massive vaginal necrosis 413

Deborah C. Gallup, MD, Thomas E. Nolan, MD, David Martin, PhD, MD, Donald G. Gallup, MD, and Donald M. Sherline, MD
Augusta, Georgia

A case of thrombotic thrombocytopenic purpura first seen as vaginal necrosis is reported.

Association of immunoreactive eosinophil major basic protein with placental septa and cysts 416

Terri L. Wasmoen, PhD, Carolyn B. Coulam, MD, Kurt Benirschke, MD, and Gerald J. Gleich, MD
Rochester, Minnesota, and San Diego, California

Plasma major basic protein concentration is related to the number of placental septa and cysts in pregnant women.

A case report of massive vulvar edema during tocolysis of preterm labor 420

Clark Brittain, Maj, MC, USA, Jay W. Carlson, Cpt, MC, USA, Dan L. Gehlbach, Maj, MC, USA, and Andrew W. Robertson, Maj(P), MC, USA
El Paso, Texas

Described is a case report of massive vulvar edema that occurred during tocolysis and necessitated delivery by cesarean section.

Uterine activity after preterm premature rupture of the membranes 422

B.A. Campbell, MD, R.B. Newman, MD, and S.L. Stramm, RN
Charleston, South Carolina

The daily uterine activity pattern preceding onset of preterm premature rupture of the membranes is similar to that seen in preterm labor with intact membranes.

Contents

Obstetric complications in a patient with Bernard-Soulier syndrome 425

Thomas C. Peng, MD, Thomas S. Kickler, MD, William R. Bell, MD, and Emily Haller, MD
Baltimore, Maryland

We describe the obstetric complications and management of a multiparous patient with Bernard-Soulier syndrome.

Acute cutaneous vasculitis associated with prolonged intravenous ritodrine hydrochloride therapy 427

Stacie Bosnyak, MD, Joseph M. Baron, MD, and James Schreiber, MD
Chicago, Illinois

Acute cutaneous vasculitis, confirmed by biopsy, developed in a patient after 5 weeks of intravenous ritodrine therapy for preterm labor.

■ Current Development

The three most common occupational exposures reported by pregnant women: An update 429

Yedidia Bentur, MD, and Gideon Koren, MD
Toronto, Ontario, Canada

Many uncertainties are encountered in counseling women with occupational exposures during pregnancy; the approach of the Motherisk Program and a literature update are presented for the three most common occupational exposures inquired about by pregnant women.

BASIC SCIENCE SECTION

Effects of vibration frequency and tissue thickness on intrauterine sound levels in sheep 438

Douglas S. Richards, MD, Robert M. Abrams, PhD, Kenneth J. Gerhardt, PhD, and Mary E. McCann, MA
Gainesville, Florida

Increasing vibration frequency and thickness of intervening maternal tissues in ewes significantly reduced intrauterine sound pressure levels produced by a vibromechanical device.

The interaction of electrosurgical bipolar forceps and generators on an animal model of fallopian tube sterilization 443

Robert D. Tucker, PhD, MD, Jo Ann Benda, MD, Ali Mardan, PhD, MD, and Tibor Engel, MD
Iowa City, Iowa, and Denver, Colorado

The important variable relating to efficacy in electrosurgical bipolar tubal sterilization is the energy delivered to the tissue, not the generator or forceps used.

Fetal hypertension induced by norepinephrine infusion and umbilical artery flow velocity waveforms in fetal sheep 450

Hans van Huisseling, MD, Guido J.J.M. Muijsers, MD, Jelte de Haan, MD, PhD, and Tom H.M. Hasaart, MD, PhD
Maastricht, The Netherlands

Fetal hypertension induced by norepinephrine has no effect on umbilical artery pulsatility index and placental vascular resistance in the fetal lamb.

Inhibition of oxytocin-induced uterine contractions by an oxytocin antagonist in the pregnant baboon 456

Laird Wilson, Jr., PhD, Michael T. Parsons, MD, and George Flouret, PhD
Chicago, Illinois, and Tampa, Florida

An oxytocin antagonist effectively inhibits uterine contractions induced by oxytocin in the pregnant baboon.

The prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the families of couples with recurrent spontaneous abortions or gestational trophoblastic tumors 461

Hong-Nerng Ho, MD, Thomas J. Gill III, MD, Chang-Yao Hsieh, MD, Yu-Shih Yang, MD, and Tzu-Yao Lee, MD
Taipei, Taiwan, and Pittsburgh, Pennsylvania

There is an increased prevalence of recurrent spontaneous abortions, cancer, and congenital anomalies in the families of couples with recurrent spontaneous abortions or gestational trophoblastic tumors.

The mechanism responsible for diminished neutrophil production in neonates delivered of women with pregnancy-induced hypertension 467

Joyce M. Koenig, MD, and Robert D. Christensen, MD
Salt Lake City, Utah

The neonatal neutropenia after maternal pregnancy-induced hypertension is associated with the presence of an inhibitor of neutrophil production.

Hemorrhage-induced reductions in plasma atrial natriuretic factor in the ovine fetus 474

Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD
La Jolla, California

Blood volume reduction lowers plasma atrial natriuretic factor concentrations in the ovine fetus.

"Just as good as Corometrics' Qwik Connect Spiral™ Electrode and it costs less."

Believe it or not, we're flattered when our competitors use this approach to sell their products. They are, after all, conceding that Corometrics' Spiral Electrode is *The Gold Standard.*

Imitations aren't always so flattering, especially if they don't perform to the clinical standards that your staff has come to know and trust with Corometrics. No price differential can make up for that. The convenience and reliability of the Corometrics' Qwik Connect Spiral System is worth a few pennies more.

So don't let the imitators fool you. Copies are just that. They're not the real thing nor will they ever be *The Gold Standard.*

Choose the spiral system that is in the best interest of your staff and your patients. Choose Corometrics, the largest single supplier of fetal electrodes in the world.

Whether it be our Qwik Connect Spiral or our standard spiral system, the choice is yours.

Corometrics has always provided top quality products at competitive prices.

If you have any questions about the *New* Qwik Connect Spiral or would like to place an order, please call the **SPIRAL HOT LINE** at **800-243-3952, ext. 452** or write Corometrics Medical Systems, Inc., 61 Barnes Park Road North, Wallingford, Connecticut 06492-0333.

Advances in health science often come from the successful combination of individual elements that, taken together, are more powerful than any one alone. That is as true in science as in business.

This is why the company you've known as Reid-Rowell has now become Solvay Pharmaceuticals—adopting the name of our $8 billion-strong, Belgium-based chemical and pharmaceutical parent company, Solvay & Cie. As part of the human health division we share a proud 128-year heritage of pioneering research in chemistry, biology and pharmacology. We benefit from the resources, global reach and commitment to research and development of Solvay's human health division.

You already know us for our work in gastroenterology and endocrinology, for Rowasa®, Creon®, Duphalac®, Estratest® and other pharmaceuticals. At our headquarters in Marietta, Georgia, scientists have embarked on full scale development efforts for new products to treat diseases of the cardiovascular, endocrine, gastrointestinal and central nervous systems. We're turning research into results to deliver tomorrow's medicines.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

> *Examples* (if six or fewer authors, list all; if seven or more authors, list three then et al.):
>
> JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.
>
> BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.

—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.

—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.

—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.

—Human experimentation has been approved by the local institution as stated in the Methods section.

—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.

—The covering letter with essential information is with the manuscript.

—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.

—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.

—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.

—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.

—Title.

—Author(s) name(s) and highest academic degree(s) are shown.

—City(ies), state(s), and country other than U.S. in which the study was conducted are given.

—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.

—Acknowledgment of financial support is cited.

—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.

—If reprints will not be available, this has been stated on the title page.

—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.

—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.

—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

- Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
- Tables are cited in sequence in the text.

Figures

- Each is numbered with an Arabic numeral and cited in numerical sequence in the text.
- Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

- Are typed double-spaced.
- Are numbered consecutively in the order they are cited in the text.
- The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.
- Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

The responsible author(s) must be named________________________ ________________________

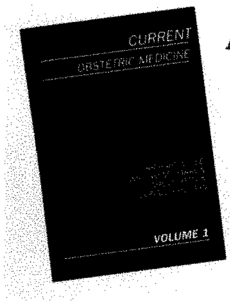
Current Obstetric Medicine, Volume 1
Premier Edition

In the Pregnant Patient + Medical Disorder equation, where do you fit in?



A pregnant patient with a medical disorder poses a unique and special challenge. You need to understand her disease and how it affects her pregnancy. You also need to recognize the physiologic signs of a normal gestation in order to best treat her overall condition.

In this premier volume of **Current Obstetric Medicine**, international authorities discuss recent developments in obstetric medicine, summarizing pertinent findings and trends from the literature published within the last two years. They also add their own critical commentary, providing new perspectives on the problems you face. Concentrating on emerging treatments and insights, the authorities focus on how these innovations affect your patients and your practice. This combination of the latest research and expert interpretation makes **Current Obstetric Medicine, Volume 1** a vital clinical reference.

You'll get a multidisciplinary perspective of new diagnostic techniques and therapies, such as preconception counseling and management of asthma, rhinitis, and anaphylaxis during pregnancy. A wide spectrum of conditions and problems are covered, including renal disease, postpartum thyroiditis, diabetes, and accidents. And each issue in **Current Obstetric Medicine** is discussed in terms of its clinical significance – so you can start applying the best available treatments to your patients' care immediately.

To review this outstanding resource ***free for 30 days****, simply mail the Free Examination Certificate below or call* ***Toll-Free 1-800-426-4545*** *(To speed your order, mention code "MCA-029"). If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It's an easy way to place yourself in the patient care equation.*

FREE EXAMINATION CERTIFICATE

Please send me **Current Obstetric Medicine, Volume 1** (21178). I understand that I will pay $59.95* plus shipping and handling if I decide to keep the book.

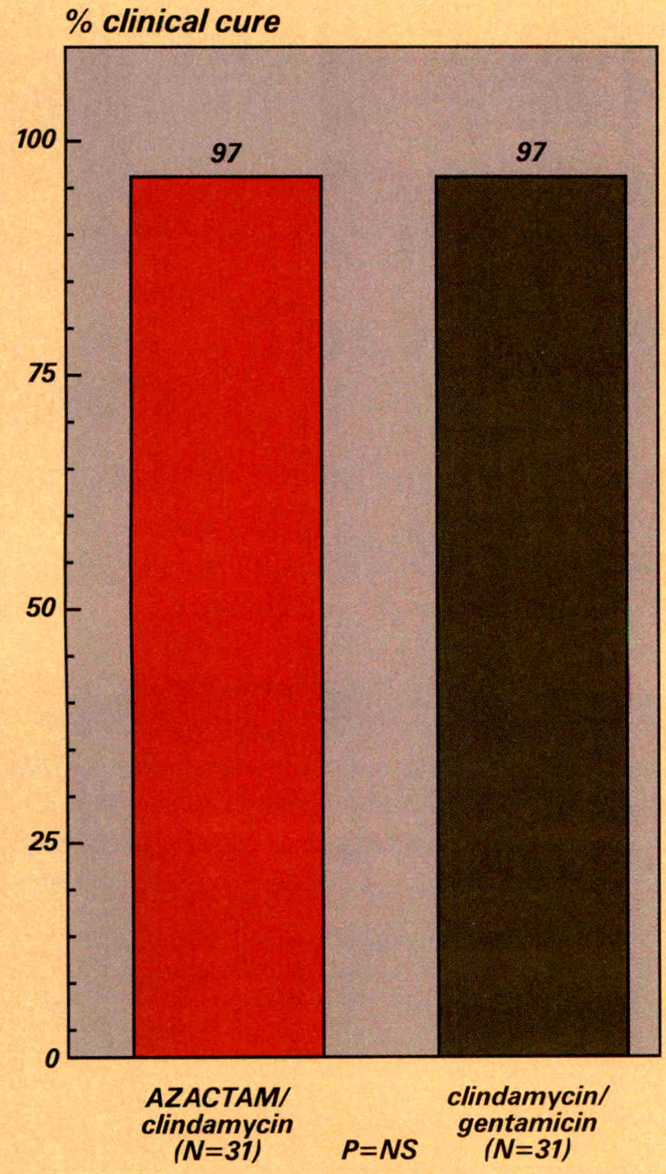
When you purchase, we'll send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you do not want the Current, the advance notice makes it easy for you to let us know. And if you elect to receive the new Current, you need do nothing. We will send it on publication. No worry. No wasted motion. And, of course, every Current is yours to examine free of charge for 30 days.

IN POSTPARTUM ENDOMETRITIS*



A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.

‡Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.*[†]
- *Greater than 90% cure rates in combination with clindamycin.*[1-3]
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.*[‡]
- *Pregnancy Category B.*

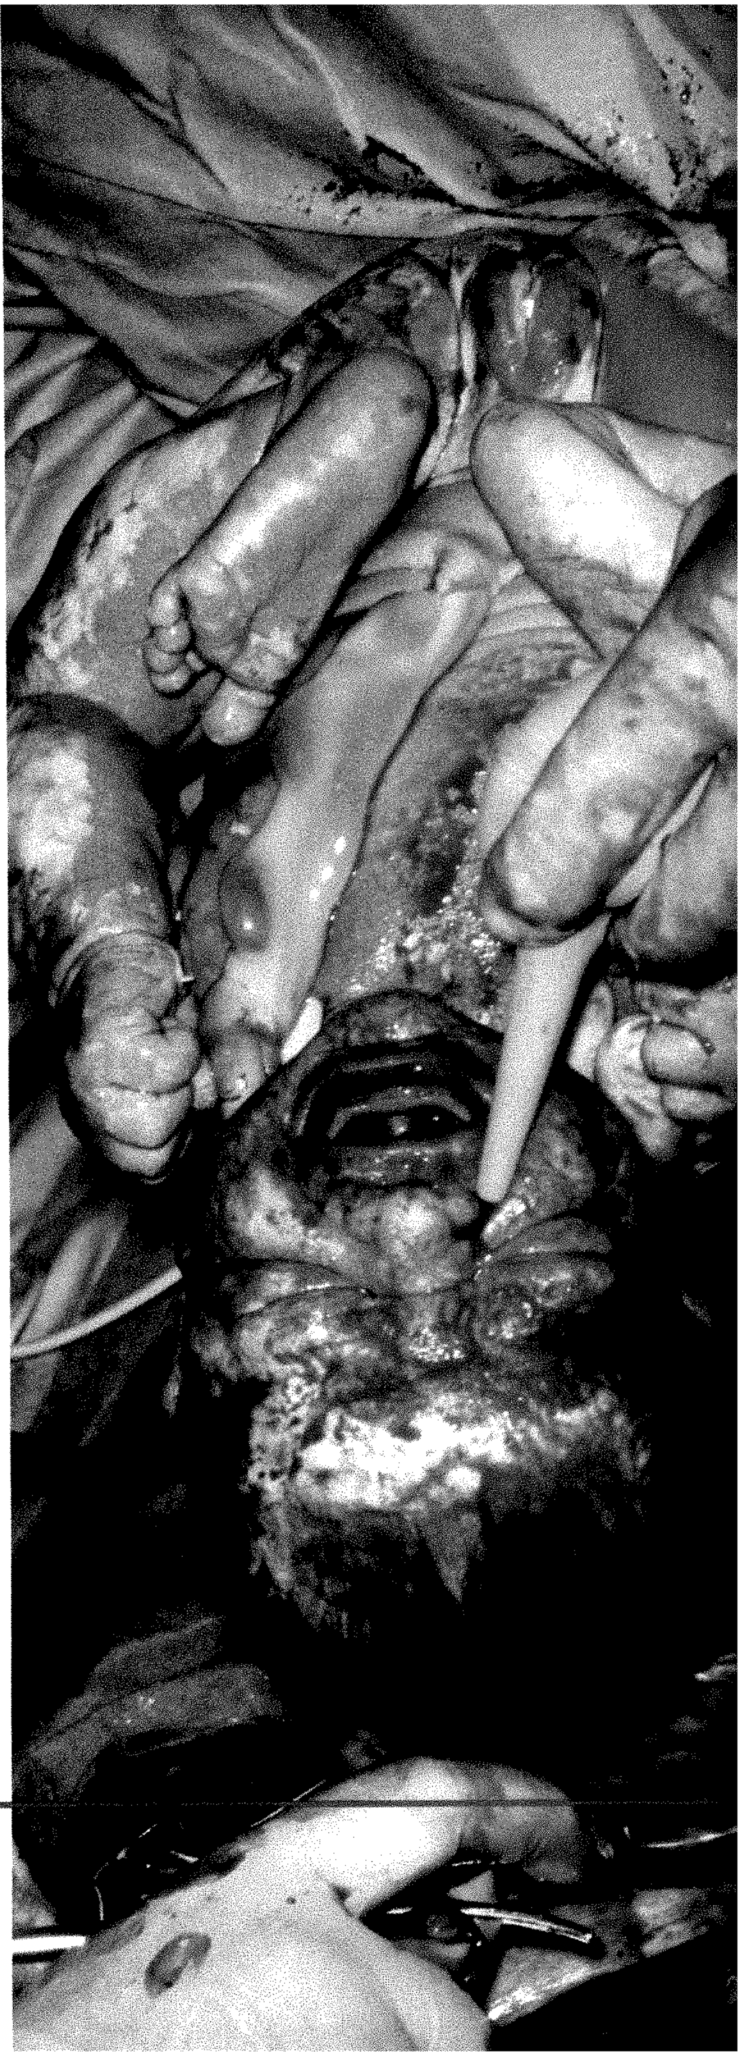
There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

Azactam®

aztreonam

A logical alternative to aminoglycosides.

Please see adjacent page for brief summary of prescribing information.



Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

TRANSACTIONS OF THE FIFTY-THIRD ANNUAL MEETING OF THE SOUTH ATLANTIC ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Our shield: Competence with compassion

Presidential address

M. Tucker Laffitte, Jr., MD
Columbia, South Carolina

Our organization has been blessed with a wonderful heritage. The "town and gown" leadership has worked well. Today, as never before, we must act in concert with other professions and other public bodies in an effort to deliver excellent health care in an environment we all enjoy.

Improved patient care has always been the thrust of our education, but in recent years the cost of this care has become a dominant factor. The excellent quality of health care in this country is recognized throughout the world, but the public and business community have become alarmed by the ever-escalating cost.

Of equal concern is the stated lack of medical care available to a significant number of our population. Our aging society poses additional stress on the so-called "health-care dollar." In 1980, those over 65 years of age numbered 25 million. By the year 2025, that number will increase to 60 million. This fact alone reminds us of the importance of preventive medical health care. Ideally, we would all like to die in a state of good health.

The advice we give does have an impact in improving the health of women. Teenage counseling and education lower the incidence of sexually transmitted disease and unplanned pregnancies. The yearly Papanicolaou smear has almost eliminated death from cancer of the cervix. Screening for diabetes and other metabolic conditions has allowed for earlier diagnosis and treatment. The detrimental effects of tobacco and alcohol are being emphasized. Genetic counseling has allowed patients to anticipate obstetric outcome. Estrogen replacement in postmenopausal patients lowers mortality by decreasing osteoporosis and improves the quality of life. Improved diet and exercise lower the incidence of cardiovascular disease. Mammography gives us a tool that lowers the mortality from breast cancer. Fewer prescriptions from us decrease the incidence of drug dependence. Informing our patients will require some adjustment on our part as these endeavors are time-consuming.

In 1989 *U.S. News and World Report* rated United States hospitals as to which were best. I suspect that we too are being rated. Do we improve patient care? Do we influence costs? Do we influence quality? Do we in general foster and stimulate improvements in the health care of women who properly come within the parameter of obstetrics and gynecology? These are the purposes that were stated more than 50 years ago by the founders of this organization. These continue to be our purpose; however, many changes have occurred in our society and our profession since its organization.

Before World War II, women were rarely included in our work force or professional ranks. Two-parent families were traditional. Before 1973, elective abortion was illegal. Sexuality was a private matter. Homosexuality was an abnormal state, and sex within marriage was hallowed. There was respect for our institutions: the church, the legal profession, and the medical profession. All have suffered a great deal in the last few decades.

It is said that one third of our population is deprived of adequate medical care. What is our role in assuring care to all members of our society? The public has

6/6/30070

stepped in to "fill this so-called void." Politicians have become very vocal and great amounts of money have been spent. To maintain our credibility, we should be advocates for keeping our patients' costs down and avoiding business partnerships that are profit-driven.

Technology has allowed many women to conceive and deliver babies in cases where this would have been impossible years ago. This same technology has allowed infants to survive who formerly would have perished before the advent of neonatal intensive care units. Withdrawal of life support continues to be controversial. These and other problems have caused us to discuss the rationing of medical care on the basis of cost.

Identifying the challenges seems to come easy for all of us. The solutions are more elusive. The responsibility rests squarely on our shoulders because there is no other group that can perform the duties of our specialty. The answers will not come easily, but competence, compassion, caring, and consideration are qualities that we must demonstrate. It is within this spirit that we need to work with other members of our society in reaching solutions.

The fact that our members prepare and present original articles during this meeting is evidence of a commitment to communicate and a hunger to acquire knowledge. Continued education is a trademark of good medical care. Attendance at society meetings is an indication of a desire to provide a more enlightened level of care for our patients. This is commendable.

We have passed through a period of cynicism when no one respected doctors, clergymen, or any other professions. Our patients have been identified as "clients," and we have been labeled "vendors." I, as probably you, find these labels to be very offensive, but with the passing of time we have come to realize that change must be met with understanding rather than "knee-jerk" reaction. When most of us entered practice, there existed a strong physician-patient bond that was based on trust and respect, especially in obstetrics. The majority of young fathers today seem to enjoy being with their wives during the childbirth experience. Many advocates felt that so-called "bonding" would reduce the distressingly high divorce rate, but that has not proved to be the case. How can we make a difference?

Most of us have come from families that have given us strength and support. We are well educated and motivated to carry out our jobs to the best of our ability. It has been and still is our privilege to be physicians, and it remains our responsibility to care for all members of our society, regardless of ability to pay. We have made sacrifices to attain our professional status; however, we must continue to sacrifice ourselves if we are adequately to understand and care for our patients' needs.

In our age of sophisticated technology, we must remember to be compassionate. Dr. Charles Bryan[1] in the April 1990 issue of *The South Carolina Medical Journal* recalled an incident during his residency. The patient was a frail, elderly woman with acute myocardial infarction. She was going into shock, and he called a cardiologist. Entering the intensive care unit, having never seen the patient before, the cardiologist abruptly announced: "Mrs. Jones, I'm Dr. Smith, and I'm going to put this catheter in your heart." Dr. Bryan went on to state that many persons would criticize Dr. Smith on the grounds that this approach to the patient epitomized our profession's present-day shortcomings, namely, that we have made great strides in technical proficiency but along the way have lost our human touch. However, he goes on to defend "Dr. Smith" in that our first obligation to our patients is to perform competently that which we do.

At one extreme those reimbursed primarily for procedures do their patients a disservice to the extent to which "compassion" is omitted from the competent performance of those procedures. At the other extreme, those reimbursed primarily for rendering compassion (such as pastoral care-givers) do patients a disservice when competent technology is sacrificed. The truly wonderful thing about medicine is that most of us can do both. But in striking a balance we should always strive to do well that which we are actually paid to do.

Compassion alone is not sufficient. We must have: (1) courage (which makes everything possible), (2) competence (which establishes credibility), (3) consistency (which ensures that competence will become reality), and (4) compassion. However, we should be aware that "compassion without competence at what one claims to be able to do is fraud; consistent application of competence is compassion."

Let us be positive. The secret of caring for the patient is to be able to do something for the patient and to do it well. Never before has it been possible to do so much for so many.[2]

Yes, it is our role as physicians to keep pace but never forget the patient in the provision of health care. We will not be able to fill all the needs and we must recognize that, unfortunately, we will be confronted with situations that are out of our control.

And, yes, it is the personal application of our skills that has made our profession what it is today, and it is continued care and concern that will allow us to be judged fairly.

In closing, may we remember what a friend reminded me—"that a patient doesn't care how much we know, but she must know how much we care."

Characterization of in vitro chemosensitivity of perioperative human ovarian malignancies by adenosine triphosphate chemosensitivity assay

Robert T. Gerhardt, MPH, James P. Perras, PhD, Bernd-Uwe Sevin, MD, PhD, Edgar Petru, MD, Reinaldo Ramos, BS, Lucy Guerra, and Hervy E. Averette, MD
Miami, Florida

We report the in vitro chemosensitivity of primary and recurrent human ovarian tumor samples analyzed by adenosine triphosphate chemosensitivity assay. We defined sensitivity as a ≥70% decrease in intracellular adenosine triphosphate versus control at 20% of the reported peak plasma concentration per agent tested. Twenty of 21 assays (95.24%) were completed successfully. Single-agent and combined dose-response patterns consisting of decreasing viability with increasing drug concentration were observed consistently. Thirteen primary tumors were assayed, with 15.4% sensitive to cisplatin, 7.7% sensitive to 4-hydroxycyclophosphamide and 53.8% sensitive to their combination. Seven recurrent tumors were assayed, with 14.3% sensitive to cisplatin, 28.6% sensitive to 5-fluorouracil, and 42.9% sensitive to their combination. Dose-response characteristics and in vitro sensitivity rates reported in this article are consistent with reports of patient response in the literature. We conclude that adenosine triphosphate chemosensitivity assay is an efficient and reliable instrument for the in vitro chemosensitivity assessment of human tumors and warrants further clinical investigation. (Am J Obstet Gynecol 1991;165:245-55.)

Key words: Adenosine triphosphate chemosensitivity assay, bioluminescence, chemosensitivity, ovarian cancer

Researchers and clinical oncologists have long recognized the potential value of pretreatment assessment of chemosensitivity for patients with cancer.[1] Efforts in this direction to date have produced mixed results.[2] The issues of in vitro evaluability, heterogeneity of tumor subpopulations,[2] emerging drug resistance,[4] and the questionable role of clonogenic or stem cells in malignancy have provided formidable obstacles to the development of an in vitro assay possessing in vivo predictive value. Assays such as the human clonogenic assay, succinate dehydrogenase inhibition, and radioactive thymidine uptake index are often inconclusive, and they possess a high rate of nonevaluability.[5-7] Consequently, in vitro chemosensitivity testing to date has remained primarily within the purview of the basic scientist, leaving the clinician to select chemotherapeutic regimens on an empiric basis.

Ovarian malignancy is a formidable disease for the patient and a challenge for the clinician. Its insidious onset with relatively late detection, high malignant potential, tendency toward early metastasis, and rapid development of resistance to chemotherapy contribute to a generally poor prognosis for the afflicted patient.[8] The standard treatment for both primary and recurrent malignancy includes cytoreductive surgery followed by adjuvant chemotherapy with one or a combination of several agents, commonly including cisplatin and cyclosphosphamide. 5-Fluorouracil (5-FU) is sometimes used in the salvage therapy of recurrent malignancies. Prognosis is related to clinical stage, histologic grade, tumor type, the amount of unresectable residual tumor at the time of cytoreductive surgery, and response to postoperative adjuvant chemotherapy.

The adenosine triphosphate (ATP) chemosensitivity assay has been reported as an efficient, highly evaluable, and cost-effective means of characterizing the in vitro chemosensitivity of cell lines and fresh human tumors, with promising preliminary clinical correlations.[9-11] With ATP extraction by acid cytolysis and measurement by luciferin-luciferase bioluminometry, ATP chemosensitivity assay assesses chemotherapeutic-induced cell kill of the entire tumor sample (including proliferative and nonproliferative subpopulations) by comparing total ATP concentration in treated samples versus untreated controls. Total ATP concentration as

assessed by ATP chemosensitivity assay demonstrates a strong correlation with in vitro viable cell count ($R^2 > 0.95$).[9-11]

This study was designed to assess critically the use of the ATP chemosensitivity assay as an in vitro model of human tumor chemosensitivity. Both primary and recurrent human ovarian carcinomas obtained intraoperatively were analyzed over a wider range of chemotherapeutic dosages than in prior studies to more accurately characterize chemosensitivity and the related phenomena of drug resistance, heterogeneity, and single- versus combined-agent effects. In addition, in vitro chemosensitivity rates obtained by ATP chemosensitivity assay were compared with clinical reports of patient response to identical single agents and combinations to determine whether the in vitro results were consistent with clinical experience.

Material and methods

Tumor tissue specimens were obtained from 21 patients who underwent exploratory laparotomy for surgical staging and cytoreduction of ovarian carcinoma at the University of Miami/Jackson Memorial Medical Center between Feb. 12, 1988, and Nov. 31, 1989. Primary ovarian carcinoma was diagnosed in 14 of these patients whereas recurrent ovarian cancer was diagnosed in seven. The biopsy specimens were obtained under sterile conditions from fresh tumors immediately after resection. Samples were subjected to ATP chemosensitivity assay, which is described in detail in a prior publication.[10] Briefly, ATP chemosensitivity assay begins with mechanical disaggregation followed by gentle enzymatic disaggregation, which yields a suspension of single cells and small clusters of up to 30 cells each. The cell suspension is then plated over a soft agar underlayer in standard 24-well culture plates. The agar underlayer allows growth and proliferation of neoplastic cells, but impedes the survival of nonneoplastic tissues by preventing anchorage. Varying concentrations of individual chemotherapeutic agents and combinations are then applied to the wells in triplicate. After a 6-day incubation period, intracellular ATP is extracted by trichloroacetic acid cytolysis, followed by buffering of the resultant solution and luminometry using a luciferin-luciferase enzyme complex. This complex generates quantifiable light energy when bound to ATP molecules. The average luminosity of drug-treated wells versus controls is then compared to characterize the cytotoxic effect of the drug or combination in question.

Primary tumor samples were tested for sensitivity to cisplatin, 4-hydroxycyclophosphamide (an active metabolite of cyclophosphamide) and to a combination of these two agents; recurrent tumor samples were tested for sensitivity to cisplatin, 5-FU, and to their combination. All chemotherapeutic agents and combinations were tested at final peak plasma concentration equivalents[12] of 10%, 20%, 50%, 100%, and 500% after taking into consideration a final volume composed of cell suspension, agar underlayer, and the aliquot of chemotherapeutic agent. The drug concentration calculations were based on the following 100% peak plasma concentration values reported in micrograms of agent per milliliter of plasma: 2.5 μg/ml of cisplatin, 6 μg/ml of 4-hydroxycyclophosphamide, and 50 μg/ml of 5-FU. The value for 4-hydroxycyclophosphamide represents 20% of the reported peak plasma concentration of cyclophosphamide (30 μg/ml); this reflects the resultant plasma level of this metabolite after its intrahepatic conversion.

After obtaining the bioluminescence counts and calculating the ATP concentration in each control and treated culture well, average ATP concentration and coefficient of variance were calculated for each control and treatment type–dose group. The difference in average ATP concentration between treatment and control groups was then calculated. Dose-response curves were constructed from these data. In this study, sensitivity to a chemotherapeutic agent or combination was defined as a ≥70% average reduction in ATP concentration versus control at a dose of 20% of the peak plasma concentration for the agent or combination. If a chemotherapeutically treated tumor sample failed to meet these criteria it was designated resistant to that respective agent or combination.

The concentrations of chemotherapeutic agents necessary to produce a 50% decrease of cellular ATP (IC_{50}) were calculated by median effect analysis. This method uses linear regression of the log of drug concentration versus the log of the quotient of the fraction of affected cells divided by the fraction of unaffected cells [Log (C) versus $\text{Log}(f_a/f_u)$] to produce a least-squares equation from which IC_{50} may be calculated.[13] These calculations were also used to determine the type of combined drug response pattern.

Results

During this study, 21 subject tumor tissue specimens eligible at time of surgery underwent ATP chemosensitivity assay. Twenty assays were completed successfully, yielding an evaluability rate of 95.24%. One assay displayed evidence of bacterial contamination and was excluded from the study. Among the triplicate control wells studied, coefficients of variation ranged from 2.3% to 15.9%. Sixty-five percent of all triplicate controls analyzed possessed coefficients of variation of ≤10%, whereas 95% possessed coefficients of variation of ≤15%. Greater variation was noted among chemotherapeutically treated triplicates, with coefficients of variation at 20% peak plasma concentration drug con-

DDP, Cisplatin; *4HC,* 4-hydroxycyclophosphamide. IC_{50} is reported as percentage of peak plasma concentration.

*Because of a change in laboratory procedure while this study was still in progress, combined drug concentrations for these tumors were prepared only for 10%/10%, 20%/20%, 50%/20%, and 100%/10% of cisplatin and 4-hydroxycyclophosphamide, respectively. The lack of three consecutive equivalent drug concentrations rendered it impossible to calculate IC_{50} values, thus the combination statistics were calculated without them.

Table II. Fifty percent inhibitory chemotherapeutic concentration (IC_{50}) for recurrent human ovarian carcinomas treated with cisplatin, 5-FU, and their combination

Tumor	*IC_{50} DDP*	*IC_{50} 5-FU*	*IC_{50} Combined*
MC-1	30.91	42.48	21.59

R^2 (DDP vs 5-FU)	0.45		

DDP, Cisplatin. IC_{50} is reported as percentage of peak plasma concentration.

centration ranging from 6.01% to 67.19%. Among these triplicates, 40% possessed coefficients of variation of <10%, 72% possessed coefficients of variation of <20%, and 90% possessed coefficients of variation of ≤30%.

Table I presents the IC_{50} for cisplatin, 4-hydroxycyclophosphamide, and their combination for all primary tumors analyzed in this study. Table II presents the IC_{50} for cisplatin, 5-FU, and their combination for all recurrent tumors analyzed in this study. The differential effects of single agents and their combination in the treatment of individual tumors may be assessed by comparison of the IC_{50} values; these effects are so noted. In addition, statistics are provided in each table relating to the IC_{50} distribution for each agent and combination, as well as for the coefficient of correlation between the individual agents. One will note on inspection of Table I that combined agent IC_{50} calculations are available for only seven of the 13 primary tumors. Because of a change in laboratory procedure while data collection for this study was still in progress, combined drug concentration assays for six of the 13 primary tumors included in this study were prepared in a manner that departed from the original protocol. The lack of three consecutive equivalent drug concentrations rendered it impossible to calculate IC_{50} values for these six tumors; thus the primary tumor combination chemotherapy statistics were calculated on the basis of data available for the remaining seven tumor samples only.

Tables III and IV present the comparative chemosensitivity rates of primary and recurrent tumors for single agents and combinations as assessed by ATP che-

Table III. In vitro response of primary ovarian carcinomas compared with clinical response reported in the literature

Chemotherapeutic agent or combination	*% Sensitive by ATP-chemosensitivity assay*	*Reported clinical response (complete + partial)*
Cisplatin	15.4%	6%[23] to 72%[16]
4-Hydroxy-cyclophosphamide	7.7%	5%[21] to 65%[25]
Cisplatin and 4-hydroxycyclophosphamide	53.8%	52.4%[20] to 72.0%[16]

Total tumors evaluated: 13.

Table IV. In vitro response of recurrent ovarian carcinomas compared with clinical response reported in the literature

Chemotherapeutic agent or combination	*% Sensitive by ATP-chemosensitivity assay*	*Reported clinical response (complete + partial)*
Cisplatin	14.3%	20%[15] to 72%[16]
5-FU	28.6%	9%[26] to 58%[27]
Cisplatin and 5-FU	42.9%	NA

mosensitivity assay versus the clinical response to these same agents and combinations as reported in the literature.

Fig. 1, *A*, *B*, and *C*, depicts the dose-response curves of the 13 primary ovarian carcinomas to cisplatin, 4-hydroxycyclophosphamide, and their combination, respectively. The vertical axis represents the percentage of intracellular ATP at each drug concentration versus control, whereas the horizontal axis represents the respective drug concentration as percentage of peak plasma concentration. Note the great variation of individual tumor responses and the general trend toward decreasing intracellular ATP as the concentration of chemotherapeutic agent rises.

Fig. 2, *A*, *B*, and *C*, likewise depicts the dose-response curves of the seven recurrent ovarian carcinomas to cisplatin, 5-FU, and their combination, respectively. Graph features are similar to those described for Fig. 1, as are the observations made regarding individual tumor variation and general dose-response character.

Fig. 3 depicts the response of primary ovarian tumors to cisplatin, 4-hydroxycyclophosphamide, and their combination at drug doses of 20% of the peak plasma concentration. The vertical axis represents the percentage of intracellular ATP versus control, whereas the horizontal axis depicts the different drug treatment types. The horizontal line marks the point of 70% reduction in intracellular ATP. Note the heterogeneity of response to each individual drug and the trend toward greater sensitivity to the combined regimen.

Fig. 4 depicts the response of recurrent ovarian tumors to cisplatin, 5-FU, and their combination at drug doses of 20% of the peak plasma concentration. Graph features are similar to those described for Fig. 3. Note the heterogeneity of response to each individual drug and the trend toward greater sensitivity to the combined regimen.

Fig. 5 consists of four graphs that illustrate the types of single- versus combined-agent dose-response patterns of tumors analyzed in this study. For each graph, the vertical axis represents the percentage of intracellular ATP versus control, whereas the horizontal axis depicts the concentration of the chemotherapeutic agents tested. Note the general dose-response character of each graph, with a trend toward decreasing viability as measured by intracellular ATP as drug concentration rises. The horizontal line marks the point of 70% intracellular ATP versus control.

Fig. 5, *A*, depicts an antagonistic profile, with resistance to cisplatin, sensitivity with a strong dose-response to 5-FU, and sensitivity with a less-pronounced dose-response to their combination. There appears to be a decrease in cytotoxicity of the combination (or antagonism of action) because of cisplatin. This observation is consistent with the IC_{50} calculations reported for this tumor (PO-1) in Table II. Fig. 5, *B*, depicts a subadditive profile in which resistance to cisplatin, sensitivity, a strong dose-response to 4-hydroxycyclophosphamide, and a nominal increase in sensitivity to combined therapy is observed. Fig. 5, *C*, depicts an additive profile in which one notes sensitivity and a more linear dose-response to both single agents and their combination. The combined-agent curve indicates the possibility of a greater sensitivity than to either single agent. Fig. 5, *D*, depicts a synergistic profile that has

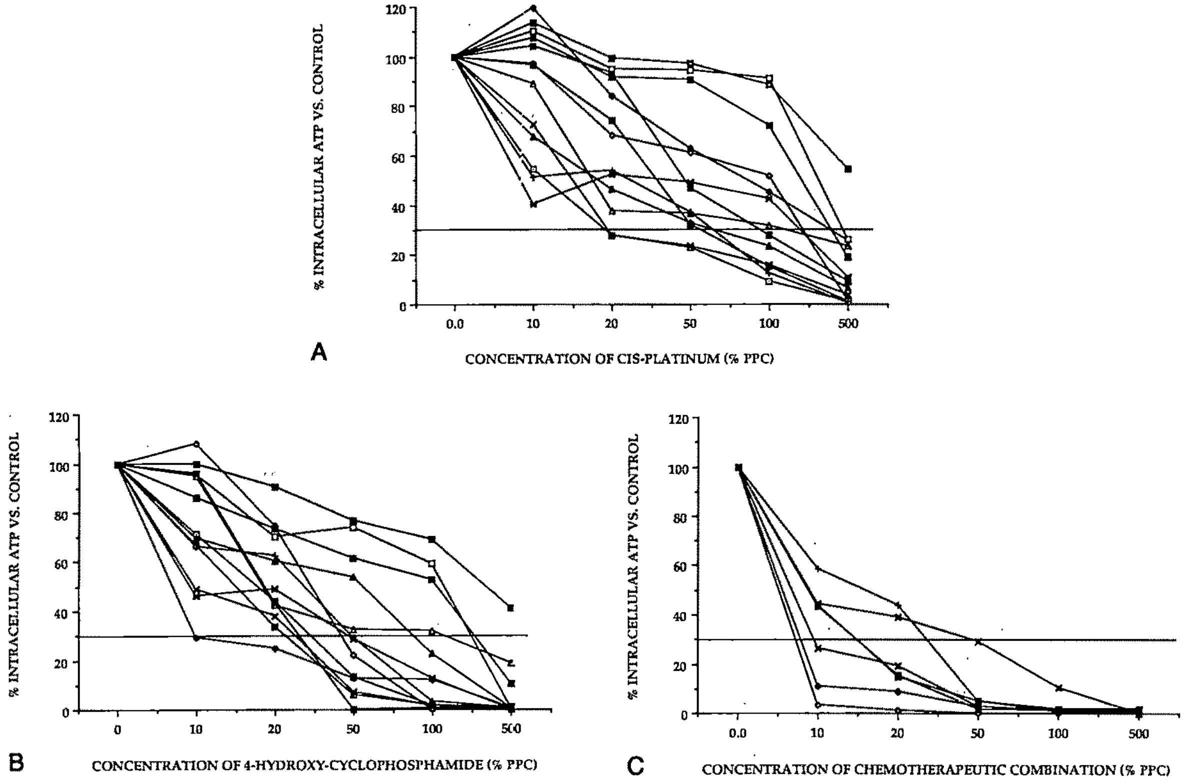

Fig. 1. In vitro chemosensitivity profiles of primary ovarian carcinomas to cisplatin, 4-hydroxycyclophosphamide, and their combination. Dose-response curves of 13 primary human epithelial ovarian carcinomas are depicted. On each graph, the *vertical axis* represents ATP concentration in chemotherapeutically treated samples as a percentage of controls. The *horizontal axis* represents the specific concentrations of each chemotherapeutic agent and combination tested, as a percentage of peak plasma concentration *(PPC)*. The *horizontal line* at 30% intracellular ATP versus control is provided as a marker of this study's criterion for sensitivity. **A**, Depicts the dose-response of the 13 primary tumors to cisplatin; **B**, depicts the dose-response to 4-hydroxycyclophosphamide (an active metabolite of cyclophosphamide); **C**, depicts the dose-response to combined exposure with both chemotherapeutic agents.

been observed on rare occasion. Resistance to both single agents up to the highest drug concentrations is noted, whereas the combined curve shows strong sensitivity at the lowest drug doses.

Comment

ATP chemosensitivity assay is an experimental method for efficiently and reliably predicting in vivo chemosensitivity on the basis of in vitro data. As developed by Perras and Sevin at the University of Miami, ATP chemosensitivity assay uses standard tissue culture materials and facilities, may be performed within a period of 6 days, and requires minimal training of the investigator beyond standard tissue culture method. With incorporation of an agar underlayer to retard growth of nonneoplastic cells, ATP chemosensitivity assay measures the in vitro chemosensitivity of human tumor suspensions representing viable cells in all stages of the growth cycle, not merely those cells that are actively proliferating. The effect of single-agent and combination chemotherapeutic treatment on tumor suspensions is assessed in terms of decreased ATP concentration present in treated wells versus controls, implying a differential in viability as a result of chemotherapeutic treatment. Preliminary clinical studies indicate a high level of predictive accuracy for the ATP chemosensitivity assay, evidenced by a strong correlation between predicted chemotherapeutic results and clinical response.[10]

Previously, we reported the chemosensitivity profiles of 22 ovarian tumor samples collected intraoperatively and exposed to chemotherapeutic concentrations of 20% and 100% peak plasma concentration, respectively.[10] The present study was designed to elucidate further the response patterns of fresh human ovarian malignancies to a wider range of chemotherapeutic doses and drug combinations. Comparison of in vitro sensitivity rates to clinical reports of patient chemotherapeutic response as found in the literature was also planned.

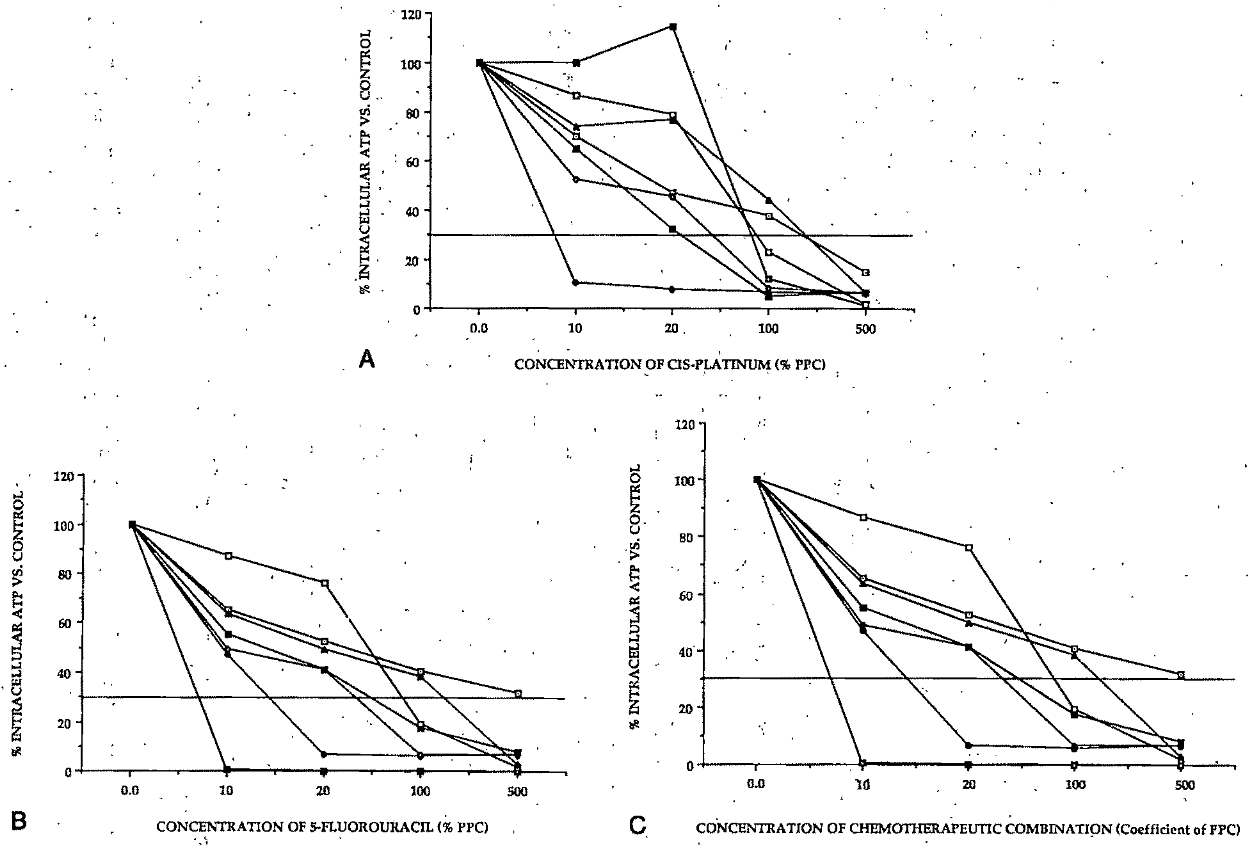

Fig. 2. In vitro chemosensitivity profiles of recurrent ovarian carcinomas to cis-platinum, 5-FU, and their combination. Dose-response curves of seven recurrent human epithelial ovarian carcinomas are depicted. On each graph, the *vertical axis* represents ATP concentration in chemotherapeutically treated samples as a percentage of controls. The *horizontal axis* represents the specific concentrations of each chemotherapeutic agent and combination tested, as a percentage of peak plasma concentration *(PPC)* as reported in the text. The *horizontal line* at 30% intracellular ATP versus control is provided as a marker of this study's criterion for sensitivity. **A,** Depicts the dose-response of the seven recurrent tumors to cisplatin; **B,** depicts the dose-response to 5-FU; **C,** depicts the dose-response to combined exposure with both chemotherapeutic agents.

Consistent with prior experiences at this facility, we observed a 95.24% evaluability rate in ATP chemosensitivity assays performed throughout this study. This success rate is significantly better than those observed with other popular chemosensitivity assays such as the human tumor stem cell assay, which possesses an evaluability rate of 40% to 70%.[2]

We selected chemotherapeutic agent concentrations on the basis of coefficients of the reported peak plasma concentrations (micrograms per milliliter) for each respective single agent after intravenous administration.[12] Peak plasma concentrations of combination treatments were based on the mixture of equivalent peak plasma concentration multiples of each of the individual agents used. The wide range (10% to 500%) and the number of data points (five) were selected to minimize interpolation and extrapolation in dose-response calculations and to provide data for subsequent correlative studies designed to determine which concentration might yield the strongest clinical predictive value. The selection of 500% peak plasma concentration also would serve a potential use because of the clinical application of intraperitoneal chemotherapeutic administration using higher doses of selected agents,[14] and would be of value in defining drug resistance.

Our decision to use a chemotherapeutic agent concentration of 20% peak plasma concentration as the in vitro predictor of in vivo tumor chemosensitivity was made on the basis of empiric findings performed at this facility. An explanation of this rationale rests with the practical estimation of a chemotherapeutic agent concentration within tumor tissue of roughly 20% peak plasma concentration resulting from the maximum possible intravenous dosage (100% peak plasma concentration). Continuous exposure to a chemotherapeutic agent at 20% peak plasma concentration is a close approximation of the area under the curve of dose versus time exposure of in vivo intravenous treatment,

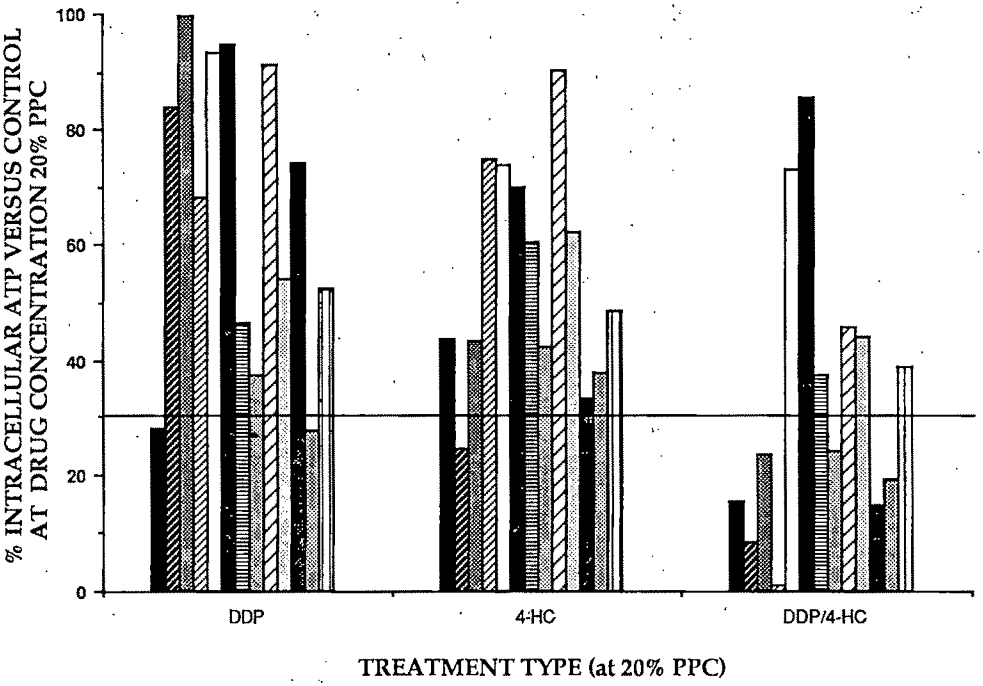

Fig. 3. In vitro response of primary human ovarian carcinomas to cisplatin, 4-hydroxycyclophosphamide, and their combination. The in vitro response of 13 primary ovarian tumors to chemotherapeutic agents at 20% peak plasma concentration *(PPC)* is depicted. The *vertical axis* represents ATP concentration in chemotherapeutically treated samples as a percentage of controls. The *horizontal axis* depicts each of three drug-treatment subgroups (*DDP,* cisplatin; *4-HC,* 4-hydroxycyclophosphamide; *DDP/4-HC,* combination therapy). The three subgroups depict the response of the 13 tumors to each individual agent and to their combination, respectively. Each tumor is represented by the same bar in each of the three subgroups. The *horizontal line* at 30% intracellular ATP versus control is provided as a marker of this study's criterion for sensitivity.

although this may vary among specific drugs and combinations.

The characterization of the chemosensitivity patterns of single and combined agents yielded interesting results. With regard to cisplatin, 15.4% of primary tumors were sensitive, whereas 14.3% of recurrent tumors were sensitive by this study's criteria. Cisplatin IC_{50}s were widely distributed for both primary (mean IC_{50}, 104% peak plasma concentration; SD, 131%) and recurrent tumors (mean IC_{50}, 29% peak plasma concentration; SD, 22%), which is consistent with the wide variation in patients' responses to this agent as observed clinically. When the two groups were compared, no significant difference was detected ($p < 0.16$). We conclude from these analyses that there is no consistent pattern of emerging drug resistance between primary and salvage treatment with cisplatin; on this basis, we infer that failure of primary cisplatin treatment would not preclude its use in second-line therapeutic regimens. This observation is consistent with clinical reports of successful cisplatin salvage therapy after its failure as a primary treatment.[15, 16]

Primary tumor response to 4-hydroxycyclophosphamide contrasted with the primary tumor response to cisplatin in several respects. Of 13 primary tumors tested, a smaller percentage (7.7%) showed sensitivity to 4-hydroxycyclophosphamide than to cisplatin (15.4%) by our criteria. Whereas wide variations were again evident, we observed a mean IC_{50} for 4-hydroxycyclophosphamide (39% peak plasma concentration; SD, 40%) that was lower than that of cisplatin (104% peak plasma concentration; SD, 131%), and that approached significance ($p < 0.11$). It is also worth noting that the deviation around the mean IC_{50} of 4-hydroxycyclophosphamide was less than that of cisplatin, indicating a somewhat greater consistency of response in this study population.

Chemotherapeutic regimens that include cisplatin and 5-FU are sometimes used in the salvage chemotherapy of recurrent ovarian carcinoma.[14-17] Generally, the response to salvage therapy is significantly less dramatic than the original therapeutic response; in the clinical environment, such therapy seldom succeeds. Of the recurrent tumors subjected to ATP chemosensitivity assay in this study, 14.3% were sensitive to cisplatin, 28.6% were sensitive to 5-FU, and 42.9% were sensitive to their combination. The observation that some recurrent tumors were sensitive to these chemotherapeu-

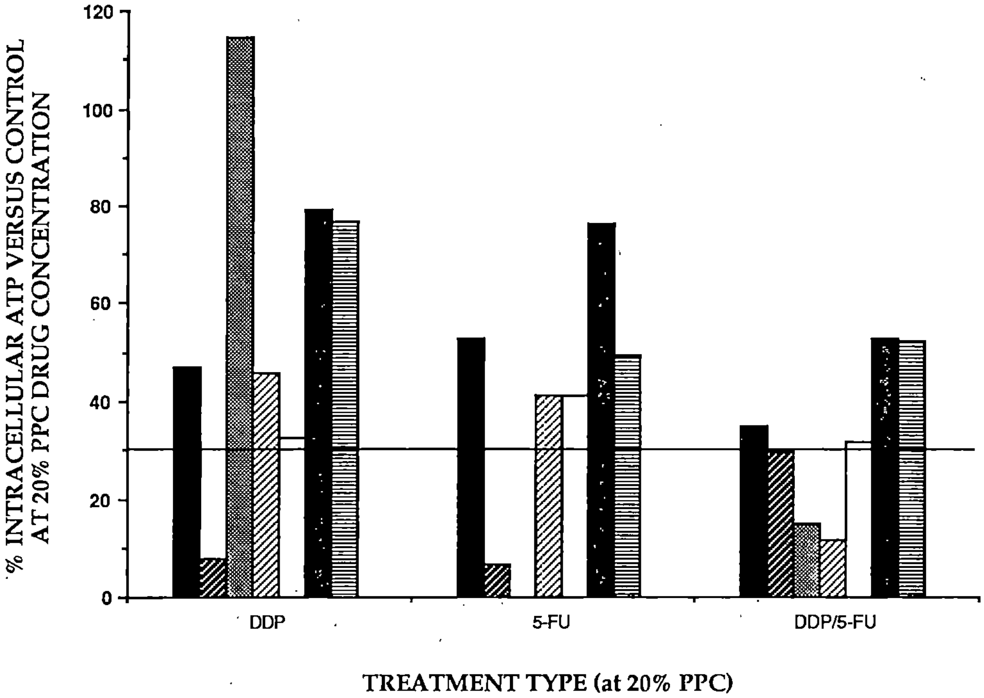

Fig. 4. In vitro response of recurrent human ovarian carcinomas to cisplatin, 5-FU, and their combination. The in vitro response of seven recurrent ovarian tumors to chemotherapeutic agents at 20% peak plasma concentration *(PPC)* is depicted. The *vertical axis* represents ATP concentration in chemotherapeutically treated samples as a percentage of controls. The *horizontal axis* depicts each of three drug-treatment subgroups (*DDP*, cisplatin; 5-FU, *DDP/5-FU*, combination therapy). The three subgroups depict the response of the seven tumors to each individual agent and to their combination, respectively. Each tumor is represented by the same bar in each of the three subgroups. The *horizontal line* at 30% intracellular ATP versus control is provided as a marker of this study's criterion for sensitivity.

tic agents shows the potential for successful salvage treatment provided that an effective agent or combination can be found. We believe this point underscores the immense potential value of the ATP chemosensitivity assay for the rapid assessment and determination of specific chemosensitivity profiles of residual or recurrent tumors on second-look laparotomy, which may differ significantly from the chemosensitivity profiles of the primary tumor. Indeed, the greatest value of ATP chemosensitivity assay may be shown in the future by its use as a means of directing salvage therapy. Here, time constraints and disease advancement necessitate the expeditious selection and undertaking of specific treatment. In such situations, ATP chemosensitivity assay could be used in the rapid screening of numerous cytotoxic agents and combinations to uncover those demonstrating sensitivity to a specific patient's recurrent malignancy.

Chemotherapy with combined agents has been shown to be more efficacious than single-agent treatment in the clinical environment.[17-20] Tables I and II show the general trend toward lower IC_{50}s for combination chemotherapy than for the constituent single agents in tumors analyzed by ATP chemosensitivity assay. Among the 13 primary tumors from which seven combined cisplatin–4-hydroxycyclophosphamide IC_{50}s were available, the mean IC_{50} for combination therapy (8% peak plasma concentration; SD, 5.6%) was lower than that of cisplatin (103.7% peak plasma concentration; SD, 131.7%), and closely approximated significance ($p < 0.075$). The mean IC_{50} for combination therapy was also lower than that of 4-hydroxycyclophosphamide (39.4% peak plasma concentration; SD, 41%); this difference closely approximated significance as well ($p < 0.062$). The seven recurrent tumors analyzed bore similar, although not as profound results: the mean IC_{50} for combination therapy was lower than that of cisplatin ($p < 0.081$); however, combined therapy did not approach significance when compared with 5-FU ($p < 0.28$). Tables III and IV show that 53.8% of primary tumors and 42.9% of recurrent tumors were sensitive to combined chemotherapeutic treatment by this study's criteria, often in the face of resistance to the same agents when tested individually. These findings are consistent with the generally accepted principle that combined anticancer chemotherapy is more effective

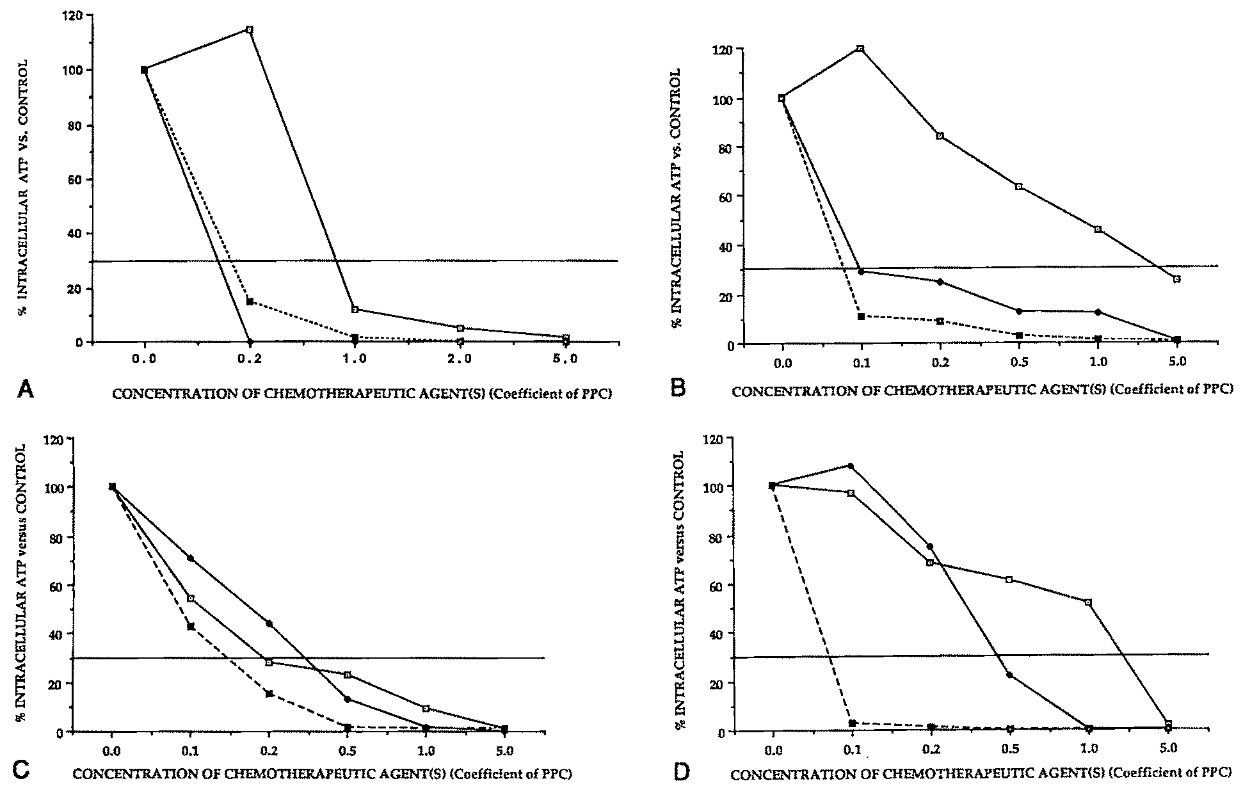

Fig. 5. In vitro dose-response profiles of individual human ovarian carcinomas to single-agent and combined chemotherapy. Dose-response curves of four representative epithelial ovarian carcinomas are depicted, showing response to two single agents and the effect of their combination on each tumor. The *vertical axis* represents ATP concentration in chemotherapeutically treated samples as a percentage of controls. The *horizontal axis* represents the specific concentrations of each chemotherapeutic agent and combination tested, as a percentage of peak plasma concentration *(PPC)*. The *horizontal line* at 30% intracellular ATP versus control is provided as a marker of this study's criterion for sensitivity. *Solid lines* represent the dose-response to single agents (*open square*, cisplatin; *solid diamond*, 4-hydroxycyclophosphamide or 5-FU, respectively), whereas the *dotted line* represents dose-response to the combination of both agents (*solid square*, combined agents). **A**, Depicts the response of a recurrent tumor sample to cisplatin, 5-FU, and to their combination, reflecting an antagonistic combined-agent profile. **B**, Depicts the response of a primary tumor sample to cisplatin, 4-hydroxycyclophosphamide, and to their combination, with a subadditive profile. **C**, Depicts the response of a primary tumor sample to cisplatin, 4-hydroxycyclophosphamide, and to their combination, with an additive profile. **D**, Depicts the response of a primary tumor sample to cisplatin, 4-hydroxycyclophosphamide, and to their combination, with a synergistic profile.

than single-agent treatment. It is also submitted as further evidence of the consistency between ATP chemosensitivity assay and clinical experience.

Tumor heterogeneity is a challenging issue in oncology.[3] The presence of unique aneuploid subpopulations within a single tumor mass has been documented by deoxyribonucleic acid (DNA) flow cytometry, whereas histochemical studies and other biochemical methods have been used to detect physiologic differences among subpopulations within a single tumor mass.[3, 21, 22] These pathophysiologic changes, most notably the acquisition of drug resistance, are clinically evident in persons in whom resistance to an agent develops during multiple treatment courses. Heterogeneity of response among histologically identical tumors obtained from different patients is also observed. This phenomenon is evidenced by populations of patients with histologically identical tumors with identical staging who respond differently to treatment with the same chemotherapeutic agent or combination.

Many of the tumors analyzed during this study showed evidence of heterogeneity as described in this article. Once again, the reader's attention is directed to Tables I and II, where wide variations in IC_{50}s are noted for different tumors treated with the same agent or combination, as well as among the different single agents tested on each individual tumor. Figs. 1 and 2 display this phenomenon graphically. In general, dose-response relationships were observed in terms of decreasing concentrations of intracellular ATP as chemotherapeutic dosage increased. The patterns of response among idividual cases, however, varied considerably. On one extreme, some tumors showed virtually complete cell kill at low chemotherapeutic doses, whereas other tumors possessed surviving fractions at drug concentrations of 500% peak plasma concentration, which would be well above the maximum intravenous concentration that could be attained in a human system. These observations show quantitatively the heterogeneity and drug resistance characteristics of malignant cell populations. They also underscore the potential value of characterizing individual patients' chemosensitivity profiles before selecting treatment.

After examining and interpreting the in vitro data, the next question we considered was whether ATP chemosensitivity assay possessed clinical relevance. Toward this end, we reviewed the literature with regard to reports of clinical response. With the use of the 70% reduction in intracellular ATP versus control at a drug concentration of 20% of the peak plasma concentration as the criterion for sensitivity, we compared the percentage of tumors sensitive to drugs by this criterion to clinical reports. Tables III and IV show these comparisons. Concerning the response of primary tumors, the in vitro drug sensitivity rates observed for cisplatin, 4-hydroxycyclophosphamide, and their combination fell within the rather wide bracket of clinically reported rates of drug response. Also, it is worth noting that the sensitivity rate to combined therapy was greater than that for either individual drug.

With regard to the response of recurrent tumors, one notes that the in vitro sensitivity rate of 5-FU fell within the bracket of clinically reported rates of drug response. The in vitro sensitivity rate of tumors to cisplatin as reported in this study was slightly lower than that of clinical reports; this may be explained in part by the limited size of our study population (seven tumors); the same may be said for the clinical reports, each of which cites fewer than 25 patients. At present, no data are published with regard to clinical response to combined cisplatin and 5-FU. Also note that the sensitivity of assayed tumors to combined therapy was greater than that reported for each individual agent. Whereas only seven recurrent tumors were evaluated in this study, the findings are consistent when compared with clinically observed responses.

At the conclusion of this study, several important hypotheses were confirmed concerning the applicability of the ATP chemosensitivity assay to human tumor chemosensitivity assessment. First, fresh human tumor evaluability rates of >95% have been obtained consistently by ATP chemosensitivity assay, confirming that it is a highly efficient instrument for the chemosensitivity assessment of intraoperative human tumor tissue specimens and is reliable in terms of evaluability. Second, ATP chemosensitivity assay dose-response patterns for tumors tested were consistent with clinical observations; namely, the assay consistently detects decreasing tumor cell viability as chemotherapeutic agent concentration rises, and it quantitatively shows that combined-agent cytotoxicity is generally equal to or greater than that observed for single agents. Further, the rates of single- and combined-agent drug sensitivity by ATP chemosensitivity assay are consistent with clinical response rates as reported in the literature, indicating that the ATP chemosensitivity assay may prove to be a reliable model for the prediction of clinical response. These observations lead us to conclude that the ATP chemosensitivity assay warrants further investigation of its predictive value in the clinical environment to determine its value as a tool in directed postoperative adjuvant chemotherapy.

We thank Bristol-Myers Co. for the donation of Platinol cisplatin preparation, and Ms. Susan Dubel for her invaluable assistance and support throughout this study.

Single-center comparison of results of 1000 prenatal diagnoses with chorionic villus sampling and 1000 diagnoses with amniocentesis

S. Robert Young, PhD, Charles F. Shipley, MD, Ronald V. Wade, MD, Janice G. Edwards, MS, Marsha B. Waters, BS, Mona L. Cantu, BS, Robert G. Best, PhD, and Edward J. Dennis, MD

Columbia, South Carolina

Large multicenter studies have confirmed the safety and accuracy of chorionic villus sampling as a prenatal genetic diagnostic procedure, but there have been few single-center evaluations. We report our experience with 1000 consecutive chorionic villus sampling procedures compared with 1000 consecutive amniocentesis procedures during the same period. The procedures were performed by the same genetic counselors, sonographers, obstetricians, and laboratory personnel. Indications for referral, demographic characteristics of patients, numbers of attempts per patient, fetal loss rates, laboratory results, and evaluation of accuracy are included. Analysis of all data suggests that chorionic villus sampling is a safe and accurate alternative to amniocentensis in our community-based teaching hospital. (AM J OBSTET GYNECOL 1991;165:255-63.)

Key words: Chorionic villus sampling, amniocentesis, prenatal diagnosis, genetic counseling

Prenatal genetic diagnosis by amniocentesis has been used successfully for >25 years. The development of chorionic villus sampling (CVS) in the last 5 years has presented an important option for patients. Because large collaborative studies have been conducted at major medical centers in the United States[1] and Canada,[2]

there is little information as to procedural complication rate, safety, and accuracy of CVS in community-based medical centers. We report our experience with 1000 consecutive CVS procedures compared with 1000 consecutive amniocentesis procedures during the same period performed by the same genetic counselors, sonographers, obstetricians, and laboratory personnel.

Material and methods

During the period from September 1985 to July 1989, 1000 CVS procedures and >1000 amniocenteses were performed in the Department of Obstetrics and Gynecology, University of South Carolina School of Medicine. Initially, our patient population came from within a 500-mile radius because ours was the only facility in the southeastern United States offering CVS. By mid-1988, multiple centers began offering CVS; our catchment area has since decreased to a more appropriate 50- to 100-mile radius for both CVS and amniocentesis referrals.

Before each prenatal diagnosis, a genetic counselor met with the patient to record a family history, discuss general procedure, review the advantages and limitations of testing, and obtain informed consent. Patients seen early in gestation were given the option of CVS or amniocentesis. The same genetic counselors, obstetricians, cytogenetic technologists, and geneticists served both data groups.

CVS was performed as previously reported.[3] Transabdominal real-time ultrasonography was performed with a scanner (Ultramark IV, Advanced Technology Laboratories, Inc., Bothell, Wash.) and a 3.5 MHz transducer. Fetal gestational age was determined by fetal crown-rump length measurement according to the method of Robinson and Fleming.[4] All CVS procedures were carried out by one of two experienced obstetricians (R.V.W. or C.F.S.). Maternal serum α-fetoprotein value tests and midtrimester ultrasonography were suggested as routine follow-up for patients having CVS.

To compare CVS with amniocentesis, we gathered data on 1000 consecutive patients having amniocentesis during the period May 1987 to June 1989. The timing in this data group differs because approximately twice as many amniocenteses are performed in our center as CVS. Amniocenteses were performed as previously described.[5]

For the first 700 CVS studies, the direct method of chromosome analysis was used exclusively.[6] The average turnaround time for CVS direct studies was 4.2 days. Cultured analyses were completed in an average of 17 days. Amniocytes were cultured by the flask method.[7] Turnaround time for amniotic fluid cytogenetics averaged 17 days. If CVS or amniocyte studies showed mosaicism, an abnormal finding, or questionable results, additional preparations were analyzed.

Amniocentesis follow-up information was gathered retrospectively. Referring physicians were asked to review their delivery notes to provide information on pregnancy outcome. We did not contact patients in this group and therefore lack data on side effects of the amniocentesis. Postprocedural complications, as reported by our first 1000 patients having amniocentesis studied in 1976 to 1982, were compared with those of the first 1000 patients with CVS (unpublished data). Since the advent of our program, follow-up data for patients who had had CVS have been collected prospectively by sending a letter to the referring obstetrician on the expected delivery date requesting specific information such as complications of delivery, birth weight, and information regarding possible congenital malformations. Letters sent to patients who had had CVS were timed to arrive 6 weeks after the delivery date to seek information regarding complications of the procedure, delivery, growth of the baby, and comments about prenatal diagnosis.

Reports of fetal loss from each data group were reviewed and classified as early (≤4 weeks after procedure), late (>4 weeks after procedure), and remote (≥26 weeks' gestation). Every effort was made to establish the underlying mechanism of each fetal death.

Results

Indications for prenatal diagnosis for both CVS and amniocentesis are shown in Table I. Table II lists the specific single-gene disorder for which diagnoses were sought and the number of affected pregnancies. Demographic characteristics of the study population are reflected in Table III. Patients optionally provided information on their educational background and total family income, accounting for $N < 1000$ in these tables. Ninety-three percent of CVS patients underwent the procedure at 9 to 11 weeks' gestation, with 5.1% at 7 to 8 weeks and 1.2% at 12 weeks. Eighty-seven percent of patients had amniocentesis at 16 to 20 weeks, with 5.2% <16 weeks, 4.8% at 20 to 23 weeks, and 2.1% >23 weeks.

The number of CVS catheter insertions are shown in Table IV. Overall, 79% of CVS procedures were successful at first attempt. Comparatively, 99.3% of amniocenteses were successful with one needle insertion, and none required three attempts. CVS procedural attempts analyzed chronologically by hundreds show that in the first 400 studies approximately 70% of cases required one attempt. In the later stages of study, the first attempt was successful in 85% of cases. Our current practice is to stop sampling after two unsuccessful attempts.

Cytogenetic results of the 1000 CVS and 1000 amniocentesis studies are presented in Table V. No cases of chromosome, neural tube, or single-gene defects were missed by these studies. There were 22 CVS and 14 amniocenteses with aneuploid or ring chromosome results. All but one translocation were known to be familial; one balanced Robertsonian translocation found at amniocentesis remains unclassified because

the parents declined testing. One CVS result was reported as being 46,XY on the basis of direct preparation only and was discovered to be incorrect at the birth of a phenotypically normal female infant with a 46,XX karyotype. The pregnancy involving the CVS ring chromosome result was electively terminated after the direct analysis showed >20 cells to be affected. The patient opted not to wait for results from the culture. The cultured villus and tissue analysis from products of conception showed no evidence of the ring chromosome in >80 cells.

Eleven (1.1%) CVS studies showed mosaic results. One of these pregnancies was lost before further studies could be undertaken. Of the remaining 10, nine resolved to a normal karyotypes at amniocentesis and were phenotypically normal at delivery. The CVS finding of 45,X/46,XY was confirmed by amniocentesis in a blood sample from the newborn. Two amniotic fluid samples yielded mosaic findings, both confirmed in the the newborn.

In 23 CVS studies no chromosome results were obtained. In 15 cases an inadequate sample was taken. In three cases the villi appeared to be hydropic; two of these pregnancies terminated in spontaneous abortion within weeks of sampling. In three cases an adequate sample failed to yield analyzable chromosomes for study. Twelve of these patients had normal amniocentesis results, one repeated the CVS with normal results, one amniocentesis yielded trisomy 18, and six patients declined further study. Ten amniotic fluid studies yielded no cytogenetic result. In two cases a bloody or clotted sample prevented adequate cell growth, and in two others the imminent death of the fetus was suspected to have negatively influenced cell growth.

Fetal loss relative to the number of CVS catheter insertions or amniocentesis needle insertions is shown in Table VI. The percentage of loss increased significantly with catheter insertion; a 12% loss rate occurred when three passes were required. Because >99% of amniocenteses were successful with a single attempt, there was little opportunity for procedure-related trauma.

Postprocedural complications are shown in Table VII. The majority of patients with two complications reported cramping and bleeding. Pregnancy outcomes after the prenatal diagnostic procedures are presented in Table VIII. Elective pregnancy terminations included all CVS pregnancies with unbalanced, nonmosaic karyotypes, four pregnancies affected with single gene disorders, and two pregnancies in which CVS yielded no result. Four patients in the CVS group electively terminated pregnancies after abnormalities were found later (anencephaly, gastroschisis, toxoplasmosis, and trisomy 18 syndrome). Eight cytogenetically normal pregnancies were terminated without stated reasons. In the amniocentesis group, nine aneuploid pregnancies and seven pregnancies with anomalies detected by ultrasonography were electively terminated.

The percentage of loss immediately after procedures appears to be almost exactly the same in the CVS and amniocentesis groups, whereas there are small differences in the >4 weeks after procedure and at ≥26 week's gestation intervals (Table VII). Approximately 96% of both groups resulted in live births, with birth weights (mean ± SEM) of 3429 (±19) gm and 3225 (±26) gm, respectively.

Comment

Recent collaborative studies from the United States and Canada have indicated that CVS is a safe, accurate modality when practiced under certain conditions.[1,2] Medical centers reporting CVS experience have gen-

erally been large facilities with high patient volume. We were interested in exploring the safety and accuracy of CVS in a community-based teaching hospital and in comparing the advantages and disadvantages of CVS versus amniocentesis in such a setting.

The current study demonstrates a change in referral patterns, in that patients of advanced maternal age are opting more often for CVS than for amniocentesis. Indications for referral revealed that 86% of patients having CVS and 55% of patients having amniocentesis underwent prenatal testing for advanced maternal age indications; 84% of the first 1000 patients having amniocentesis at our center were indicated for age-related risk.[6] Changing referral patterns are also suggested in that 32% of our patients having amniocentesis were indicated for study because of an abnormal maternal serum α-fetoprotein value, an indication that barely existed just 5 years ago. Also of note, 9% of patients of advanced maternal age underwent amniocentesis after a high or low maternal serum α-fetoprotein result became a risk factor. The development of high-quality prenatal ultrasonography has also created an indication for testing in the second and third trimesters with the discovery of anomalies on ultrasonography. Patients with histories of aneuploidy, single-gene disorder, chromosome translocations, and anxiety opted more often for CVS than for amniocentesis, whereas patients at risk because of a history of spontaneous abortion more often chose amniocentesis, perhaps from concern over procedural safety.

The demographic differences between the two data groups were highly significant (race $\chi^2 = 277.05$, $df = 2$, $p < 0.01$; education $\chi^2 = 93.06$, $df = 3$, $p < 0.01$; income $\chi^2 = 121.79$, $df = 3$, $p < 0.01$). The amniocentesis population closely resembled the overall white to black birth ratio in South Carolina (60% to 40%); in contrast, the CVS group was 90% white, with more education and a higher average family income than the amniocentesis population. This perhaps reflects the trend that educated patients with higher incomes are the first to use new testing services and may reflect the general population more accurately as CVS becomes a standard procedure.

Our study clearly demonstrates that amniocentesis is almost always successful on the first attempt and that CVS often requires two attempts. Our CVS data and those of other authors support the concept that there is a short learning curve in performing CVS, with fewer attempts and better samples as operator and sonographer experience increases.[8, 9] We currently get adequate samples on our first attempt in 89% of cases (CVS patients 1001 through 1286).

Bleeding after CVS was the most frequently encountered postprocedural complication. Patients who had amniocentesis had cramping more frequently. Although three patients who had had CVS reported fever, only one CVS pregnancy was lost by septic abortion.

Our follow-up on pregnancy outcome in the patients who had CVS is more complete than the amniocentesis follow-up and is probably due to our active solicitation of information from patients who had CVS and their physicians within weeks of delivery. Elective pregnancy termination occurred more frequently in the CVS group, which included patients who were at higher risk of having abnormalities and patients who terminated their pregnancies for personal reasons, five of which were questionably related to sex selection.

The pregnancy loss rate ≤ 4 weeks after procedure was very similar in both data groups ($t = 0.299$;

$p = 0.3821$), suggesting that procedure-related risk is similar for CVS and amniocentesis. The >4-week post-procedure loss rate was slightly higher in the CVS group and may represent the normal loss rate at this gestational age. We are unable to explain the difference found at the later stage of pregnancy. The total loss rate in both groups was 4.3%.

The pregnancy outcomes of the first 719 of the 1000 patients having CVS presented in this study were described in detail in our previous report[3]; we found that maternal age, gravidity, quantity of villi, and gestational age apparently did not contribute to fetal loss. Chi-square analysis, however, revealed an increasing risk of fetal loss with multiple attempts at CVS ($\chi^2 = 14.8914$; $p = 0.0006$). The findings in our series are consistent with the increased risk of pregnancy loss associated with multiple catheter insertions. Birth weight was significantly larger ($t = 6.33$; $p << 0.001$) in the CVS group, as was also noted by Ferguson et al.[10] The larger birth weight may reflect differences in socioeconomic status or indications for referral.

Twenty-five years of experience has proved amniocentesis to be a highly accurate technique. The technique of CVS cytogenetic diagnosis and the estimate of its accuracy are still evolving. We began our program using only the direct method of chromosome analysis; referring physicians and patients were highly satisfied with the rapid diagnosis. As cultured CVS methods were developed to get better-quality chromosome preparations, reports of discrepancies between direct and cultured results suggested study of both. Practical limitations exist, however, in that a small villus sample might preclude both studies; the cost of two chromosome analyses increases the cost of CVS by at least 150%. Culture techniques also require a longer waiting period for results and are often reported as the patient begins the second trimester of pregnancy. The newly developed interphase cytogenetic techniques[11] might be applied to CVS, and for the direct identification of common trisomies and fetal gender might be applied to amniocentesis. This method would provide a rapid screen and, combined with a karyotyping technique, may offer an accurate, quicker, and less expensive analysis, particularly for the CVS patient who seeks first-trimester diagnosis.

Mosaic findings in CVS study will likely continue to be a problem in approximately 1% of cases. This may be the actual frequency of confined placental mosaicism in the normal population, given the consistency of its frequency across studies.[12, 13] Because most patients become anxious, they can be reassured that these findings are usually artifactual and generally resolved by amniocentesis.

Cytogenetic analyses of amniocytes rarely show pseudomosaicism or maternal contamination, whereas CVS studies often appear to be confounded by these findings. Although our experience with confined placental mosaicism is similar to that reported by other authors, we have not had the 18% to 27% rate of maternal cell contamination in cultured preparations that has been reported elsewhere.[14, 15] The incidence in our CVS group (10/1000) more closely approximates that of Hogge et al.[16] (3/600).

No false-negative or false-positive results from the CVS or amniocentesis series are known. CVS showed a ring chromosome in one pregnancy; that pregnancy was electively terminated on the basis of direct results only and may have represented a confined placental mosaicism. A CVS study incorrectly reported as 46,XY was, in retrospect, a case in which 12 cells from direct preparation yielded a clear 46 count in a patient at risk because of advanced maternal age. The morphology of the chromosomes was poor, however, and the study was miskaryotyped. These incidents serve to remind us that new technology must develop in an atmosphere of constant evaluation and investigation. When unusual findings occur, we must return to the older methods for verification or reevaluation. Patients and obstetricians like the speed of the direct chromosome study, but artifacts occur and chromosome shape may not be high resolution in nature.

Analysis of the data suggests CVS to be a safe and accurate alternative to amniocentesis in our center. Although it appears that patients at higher risk opt for the earlier CVS, amniocentesis referrals have increased since the early 1980s because of an increase in midtrimester screening by ultrasonography and maternal serum α-fetoprotein values. CVS will certainly not replace amniocentesis, particularly as our techniques for Down syndrome screening with maternal serum α-fetoprotein values, human chorionic gonadotropin, and other markers become more refined. Both CVS and amniocentesis will be used more frequently in the future as more genetic conditions become diagnosable via deoxyribonucleic acid methods. We are hopeful that with time CVS technology will be accepted as a safe, accurate, and effective obstetric procedure in the same way that prenatal diagnosis by amniocentesis has been accepted.

We express our appreciation to the class of 1991 Genetic Counseling students who spent countless hours reviewing records and collecting data for this report: Joan Conard, Robin Fletcher, Kerri Hopper, Kathy Johnson, Cari Kleeman, Ginny McRoy, and Ellen Schlenker, and to Ann Bennett, RN, for compiling and recording the ultrasonographic information.

Discussion

DR. GLENWARD T. KEENEY, Fayetteville, North Carolina (Official Guest). Since Ward et al.[1] and Simoni et al.[2] first established the clinical feasibility of CVS for fetal chromosomal analysis, there has been a concerted effort to ascertain the accuracy and the procedure-related risks of CVS compared with midtrimester amniocentesis. Both Canadian and U.S. collaborative studies on CVS reported no statistically significant difference in fetal loss rates between CVS and amniocentesis.[3-5] They did report a higher incidence of technical difficulties with CVS. Ferguson et al.[6] cited the variability in operator experience and the variability in the procedure and laboratory techniques as the main drawbacks of these trials. The series of Young et al. and of Hogge et al.,[7] Brambati et al.,[8] Ferguson et al.,[6] and Green et al.[9] appear to have a decided advantage in that each series involves a relatively large number of patients from a single center. All obstetric procedures were performed by one or two experienced operators using similar techniques of CVS sampling. Laboratory techniques were similar, clinically proved, and more consistent, with better trained and more experienced assistants.

Results obtained by these five groups of investigators appear to validate the statement of Ferguson et al.[6] Failure to make a cytogenetic diagnosis in patients who had CVS was more frequent in the Canadian trial and about equal between the U.S. study and the single-center groups.[4, 5] Maternal cell contamination of villus culture was two to three times more frequent in both collaborative series, and confined placental mosaicism was approximately equal in all the studies. Notwithstanding the rapid results obtained with direct trophoblast karyotyping, the general trend is to rely more on villus culture for accurate results.[10] Combining the direct method with villus culture optimizes quality and minimizes false-positive and false-negative findings,[11] but is is more costly and takes more time. According to Young et al., mosaicism will continue to be a problem in approximately 1% of patients having CVS.

In contrast to CVS, midtrimester amniocentesis is easier, requires fewer attempts, has a very low incidence of maternal cell contamination and mosaicism, and successfully yields a diagnosis 99% of the time.[3, 4, 6, 12] Postamniocentesis complications are also less frequent, with cramping being the most commonly reported symptom. Spotting and bleeding are seen rather frequently after CVS. In spite of these advantages a recent Swedish study revealed that midtrimester amniocentesis is perceived as a more "distressing experience" than CVS.[13] Whatever the inherent difficulties with CVS, it would seem that the technique has been reasonably perfected and that most of the technical problems have been solved. The data of Young et al. indicate a diagnostic accuracy of 97.7% for CVS, which compares quite favorably with a >99% accuracy for amniocentesis.

The safety issue, however, is more difficult to evaluate. Maternal infection is quite low with both methods, and fetal risk is the central issue. Absence of a control group in virtually all studies prohibits direct estimation of the total losses of the two techniques. Rhoads et al.,[3] who participated in the U.S. collaborative study, quote a 2.2% to 5.4% fetal loss rate after CVS in other published reports. In their own series they corrected for differences in gestational age and maternal age and concluded that the best estimate of excess risk for CVS over amniocentesis is 0.8%. The Canadian study gives a 0.6% excess loss for CVS. Green et al.[9] quote a 0.6% procedure-related fetal loss, but their study includes only those early losses in the first few weeks after procedure. Ferguson et al.[6] have a 2.4% loss after CVS and a 0.9% rate after amniocentesis up to 28 weeks. They caution, however, that the CVS loss rate does not take into account the "background fetal loss." This term refers to spontaneous losses between 9, 12, and 16 weeks in patients with normal first trimester ultrasonography and no invasive procedures.[3,6]

Table VIII in the study by Young et al. lists loss rates of 1.6% and 1.8% at 4 weeks after CVS and amniocentesis, respectively. They suggest that this may represent a procedure-related risk for the two procedures. Rates of late losses of >4 weeks but <12 weeks after procedure were 2.3% for CVS and 1.2% for amniocentesis, possibly representing "the normal loss rate at this gestational age." Presumably this is a reference to the background spontaneous fetal loss. Rates of remote losses >12 but <20 weeks after procedure were actually higher for amniocentesis (1.3%) than for CVS (0.4%). No explanation is available for this difference.

In an earlier article coauthored by Young et al.[14] and presented to the South Atlantic Association of Obstetricians and Gynecologists in 1989, data are presented on the first 719 CVS patients in the current study. The total corrected fetal loss from CVS are 4.1% in the earlier study, ≤26 weeks' gestation. The current study shows identical total-corrected fetal losses of 4.3% for CVS and amniocentesis. Although the statistics are confusing, virtually all investigators agree that CVS losses increase dramatically with the number of transcervical catheter insertions. Table VI demonstrates over a fourfold increase between one and three attempts.

What then is the procedure-related fetal loss for transcervical CVS? For midtrimester amniocentesis, the fetal risk is generally said to be 0.5%, perhaps as high as 1%.[15] Young et al. suggest a procedure-related loss in CVS of 1.6%, Green et al.[9] 0.6%, Rhoads et al.[3] 0.8%, and the Canadian series 0.6% in excess of the amniocentesis loss rate.[3,4] Transabdominal CVS, which has certain advantages over the transcervical method, has an equivalent degree of safety with the latter technique,[16,17] and controlled randomized trials are underway to compare the two CVS methods. Early amniocentesis at 10 to 14 weeks' gestation also shows considerable promise.[18] In an ongoing collaborative study by Buchanan et al. (personal communication) >3000 patients have been studied between 12 and 14 weeks with accurate cytogenetic diagnosis, minimal fetal losses, and accurate acetylcholinesterase determinations. The results on maternal serum α-fetoprotein determinations are also encouraging. The advantages of this technique are readily apparent.

It is abundantly clear that a more standardized method of reporting fetal loss rates is needed. The published statistics are often confusing, and comparisons of the relative safety of CVS with amniocentesis are frequently vague. If they are possible, prospective, controlled, randomized trials will be much more meaningful if fetal loss rates are reported in a uniform manner.

This criticism in no way detracts from the excellent work of Young et al. Their report is orderly and comprehensive and includes a large number of patients from a community-based hospital. The same experienced team performed the procedures throughout the study. Follow-up with the patients who had CVS is excellent, and there is little doubt of a future increased demand for CVS and amniocentesis. The data also support the conclusion of Young et al. that prenatal diagnosis by CVS at regional centers is a safe and accurate alternative to amniocentesis. Fetal loss, nevertheless, is probably somewhat greater with the former method.

Discussion

Dr. William Kirkley, Fort Lauderdale, Florida. Did they do amniocentesis with those patients who had high maternal serum α-fetoprotein and normal level 3 ultrasonograms?

Dr. John W.C. Johnson, Gainesville, Florida. The 6% loss rate with two catheters seems high. Did the authors think about restricting their analysis to one-catheter studies?

Dr. Fay O. Redwine, Richmond, Virginia. Would the authors say what percentage of patients having CVS had to undergo amniocentesis—the total number—to improve the accuracy of their results or for other indications later in pregnancy.

Dr. Max C. Karrer, Jacksonville, Florida. I am a little confused over your statement of a 3% baseline loss rate when there is a time differential in comparing 4 weeks after CVS and 4 weeks after amniocentesis. How can you say that you have a 3% baseline loss rate?

Dr. Young (Closing). Amniocentesis was routinely offered to patients with elevated maternal serum α-fetoprotein values, regardless of normal-appearing ultrasonography findings. Recently we evaluated the patients with elevated maternal serum α-fetoprotein values in a portion of the amniocentesis study group.[1] Our findings support the use of ultrasonographic revised risks for open neural tube defects and allowing the patient to make an informed choice in reassessing the need for amniocentesis.

The 6% loss rate with two catheter insertions does seem high; however, this series represents our first 1000 CVS cases. The number of insertions has decreased with experience, and we are hopeful that the complication rate will, too. We will continue to monitor multiple sampling versus complications; if the loss rate remains at 5% to 6%, we should restrict sampling to one attempt.

Overall, 3.3% of patients having CVS had indications for amniocentesis because of failed CVS or mosaic results. Of these, three spontaneously aborted at <16 weeks, and six patients declined further study, yielding 2.4% of the CVS study group who also underwent amniocentesis.

The 3% baseline loss rate refers to spontaneous fetal loss at all gestational ages, not limited to 4 weeks after the procedure. One insertion was associated with a 3.1% loss rate in the CVS group and 3.6% rate in the amniocentesis group. This compares with the U.S. collaborative CVS study in which one insertion related to a total fetal loss rate of 2.9%.[2] This also compares with the National Amniocentesis Registry, which evidenced a 3.5% loss rate in the study group compared with a 3.2% rate in matched controls.[3]

Quantification of cervical change: Relationship to preterm delivery in the multifetal gestation

Roger B. Newman, MD, Raleigh K. Godsey, MD, Janna M. Ellings, RN, CNM, Berry A. Campbell, MD, Daniel P. Eller, MD, and M. Clinton Miller III, PhD

Charleston, South Carolina

Prematurity is the major contributor to the very high perinatal morbidity and mortality associated with multifetal gestations. Antepartum cervical evaluation has been suggested as a way to better define the risk of preterm delivery in multifetal gestations. Weekly digital cervical examinations were performed in 86 twin and 7 triplet gestations that were being monitored in a special antepartum clinic. A cervical score was calculated from each examination by subtracting cervical dilatation in centimeters from cervical length in centimeters. Cervical scores decline gradually with advancing gestation and are influenced by parity and subsequent preterm delivery. Intervals until delivery decrease significantly with lower cervical scores. A cervical score ≤ 0 on or before 34 weeks' gestation was strongly predictive of preterm delivery (75%). Only 2 of 78 (2.6%) with a score >0 were delivered within 1 week of the examination. Cervical scoring is a simple, quantifiable, reproducible, and safe method of evaluating preterm delivery risk. An understanding of the prognostic significance of specific cervical scores may be of value in determining the need for obstetric intervention. (AM J OBSTET GYNECOL 1991;165:264-71.)

Key words: Cervical score, prematurity, multifetal gestations

Houlton et al.[1] suggested in 1982 that information obtained by antepartum cervical examination was effective in predicting the onset of both term and preterm labor in twin gestations. In 1988, Neilson et al.[2] reevaluated the predictive value of antepartum cervical assessment in a larger series of twin gestations. They determined that abnormality found at cervical examination before 34 weeks' gestation identified a group of twin pregnancies at extreme risk for preterm labor whereas a reassuring examination was rarely if ever associated with the spontaneous onset of labor within 1 week. Unfortunately, in spite of its large size, the study of Neilson et al. is difficult to translate into contemporary clinical practice. Their study group was composed entirely of African women in Zimbabwe who were all parous. In addition, their patients had gestational age assessment done primarily by Dubowitz scoring, relatively few antepartum visits, and no exposure to tocolytic therapy.[2]

The ability to better predict the onset of preterm labor would be of tremendous value in multifetal gestations because of the very high perinatal morbidity and mortality associated with these pregnancies. Prematurity is the major contributor to this increased perinatal morbidity and mortality.[3, 4] If antepartum cervical assessment can better define the risk of premature delivery in multifetal gestations, then it would be of great clinical value because of the simplicity, general applicability, and low cost of this intervention. For these reasons this study was undertaken to confirm the findings of both Neilson et al. and Houlton et al. regarding the prognostic capabilities of a quantifiable cervical score and to determine its role in the risk assessment of multifetal gestations.

Material and methods

In 1988, the Medical University of South Carolina established the Twins Clinic for women with multifetal gestations. It is staffed by a certified nurse-midwife and obstetric residents, and it is supervised by members of the maternal-fetal medicine section. Since its inception, 93 multifetal pregnancies (including 86 twin and 7 triplet gestations) have had follow-up to delivery.

The frequency of antepartum visits was established at intervals of every week or 2 weeks. At each clinic visit a digital examination was done to evaluate cervical dilatation in centimeters at the internal os, cervical length in centimeters, station of the presenting part, and consistency and position of the cervix. A cervical score was calculated as described by Houlton et al.[1] In brief, a cervical score is determined as follows: Cervical length (centimeters) − Cervical dilatation at internal os

---

(centimeters). For example, a cervix that is 2 cm long with a closed internal os gives a score of +2. A cervix that is 1 cm long with a cervix dilated 1 cm at the internal os gives a score of 0. A cervix that is 1 cm long with the internal os dilated 3 cm gives a score of −2.

Preterm birth was defined as delivery before 37 completed weeks of gestation. Preterm births included in this analysis were those occurring as secondary consequences of the spontaneous onset of premature labor or preterm premature rupture of the membranes. Fifteen patients were excluded from further analysis because of elective premature delivery. Indications for these elective premature deliveries include preeclampsia ($n = 6$), fetal growth abnormalities ($n = 4$), fetal distress ($n = 2$), documented fetal maturity ($n = 2$), and elective delivery in a case of monoamniotic, monochorionic placentation ($n = 1$). Both spontaneous and elective term deliveries (≥37 weeks' gestation) are included in this analysis. The cervical score data that follow are therefore derived from 71 twin and 7 triplet gestations.

Gestational age assessment was based on the estimated date of confinement as predicted by the first day of the last menstrual period, if confirmed by ultrasonography. When there was a discrepancy of ≥3 weeks between menstrual and ultrasonographic dating criteria, the estimated date of confinement was recalculated on the basis of the ultrasonographic findings.

Thirty-nine women received tocolytics for therapy of spontaneous preterm labor for an average duration of 19.4 ± 14.3 days. In four of these women tocolysis was successful, with a gestational age ≥37 weeks' gestation achieved, and for purposes of this analysis these are considered as term deliveries. Of the remaining patients receiving tocolytic therapy, tocolysis failed in three within 24 hours after therapy was instituted and 18 were delivered after a recurrent episode of spontaneous preterm labor. Nine women experienced preterm premature rupture of the membranes at a later date and 5 were delivered early for maternal or fetal indications.

Results are expressed as mean ± standard deviation. Analysis of the data was performed by the χ^2 test with Yates' correction, the Fisher exact test, analysis of variance for repeated measures, and the correlation coefficient. Significance was established at $p = 0.05$.

Results

The demographic characteristics of the 71 twin and 7 triplet gestations are included in Table I. Forty-four of the multifetal gestations (56%) were delivered preterm; 30 of these 44 were delivered after spontaneous preterm labor and 14 after preterm premature rupture of the membranes. The remainder (44%) were delivered at term after spontaneous labor ($n = 16$), after spontaneous rupture of the membranes ($n = 5$), or by elective induction of labor or cesarean section ($n = 13$).

Table I. Demographic characteristics of the twin ($n = 71$) and triplet ($n = 7$) gestations included in the cervical score analysis

Age (yr, mean ± SD)	25.3 ± 5.0
Race (No.)	
White	33 (42%)
Black	45 (58%)
Parity (No.)	
Nulliparous	20 (26%)
Parous	58 (74%)
Gestational age at diagnosis (wk, mean ± SD)	19.0 ± 7.0
Gestational age at initial cervical examination (wk, mean ± SD)	24.2 ± 4.0
Gestational age at delivery (wk, mean ± SD)	35.8 ± 3.2
Prenatal visits (No., mean ± SD)	9.0 ± 3.8
Cervical examinations (No., mean ± SD)	7.8 ± 3.8

There is a significant decrease in the mean cervical score with advancing gestation ($p \leq 0.001$) between 20 and 36 weeks' gestation, as demonstrated in Fig. 1. No racial differences could be identified in the cervical score data; however, Fig. 2 reveals that parous women have lower mean cervical scores, especially in later gestation, as compared with those of nulliparous women.

Table II provides the mean duration from the first appearance of any specific cervical score until delivery. The lower the mean cervical score, the shorter the time interval until delivery. The regression equation for this relationship is: Time until labor = 5.12 + 1.51 (Cervical score). The regression coefficient is significant at $p \leq 0.0001$ and the R^2 (percent of variation accounted for) is 91.3%.

Pregnancies complicated by preterm delivery also had consistently lower mean cervical scores with advancing gestational age as compared with those of women delivered at term (Fig. 3). The first appearance of a cervical score ≤0 correlated best with the gestational age at delivery ($R^2 = 0.54$). Table III presents the sensitivity, specificity, predictive values, and relative risk of preterm birth associated with a cervical score of ≤0 at or before 34 weeks' gestation. Table III also provides this analysis with respect to gestational age (20 to 28 and 29 to 34 weeks) and parity (nulliparous and parous).

Of particular note is that only 2 of 78 (2.6%) women experienced spontaneous preterm labor or preterm premature rupture of the membranes within 1 week of a cervical score >0. Preterm premature rupture of the membranes occurred in a triplet gestation at 34 weeks' gestation within 1 week of a cervical score of +1.5. Another patient with a twin gestation experienced

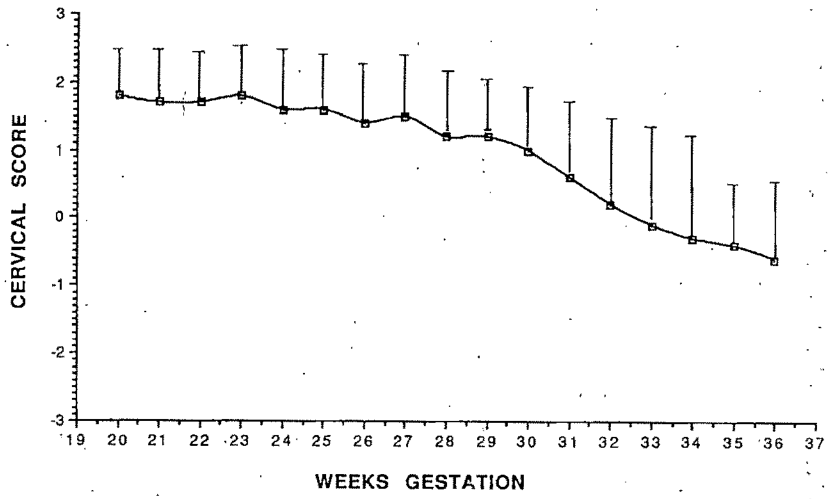

Fig. 1. Cervical score (mean ± SD) from 20 to 36 weeks' gestation for all multifetal gestations included in data analysis (N = 78).

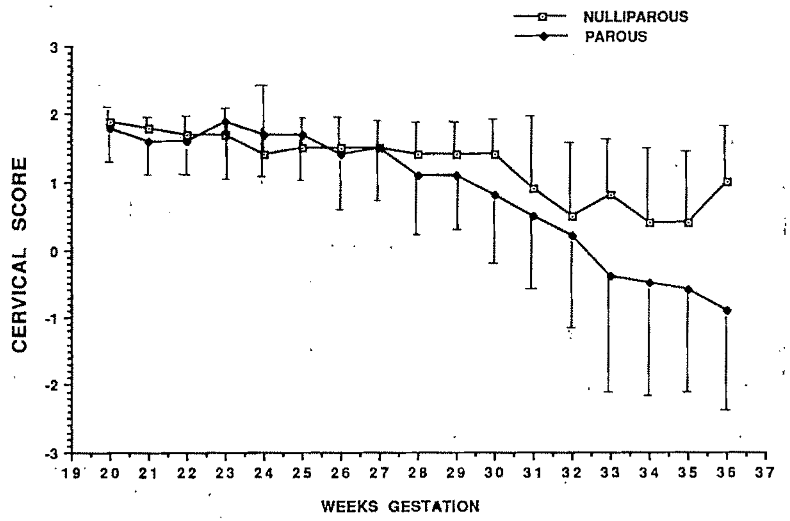

Fig. 2. Cervical score (mean ± SD) from 20 to 36 weeks' gestation for nulliparous (⊡, n = 20) and parous (▲, n = 58) multifetal gestations.

spontaneous preterm labor at 36 weeks' gestation within 1 week of a cervical score of +0.5.

Comment

Weekly cervical assessment in a group of women with multifetal gestations reveals a progressive decrease in the cervical score most notable after 30 weeks' gestation. As the cervical score decreases, the mean time until delivery shortens, and its absolute value correlates strongly with the timing of delivery. The time interval until delivery as associated with any specific cervical score in this study is very similar to the findings of Neilson et al. in their study of parous African women with twins. These similarities were found in spite of the fairly extensive use of activity restriction and tocolytic therapy in this study.

The high rate of preterm birth in multifetal gestations is a result of increased uterine activity presumably caused by myometrial overdistention.[5, 6] Cervical ripening can occur independently of uterine contractions as it is known that both endocrine factors and prostaglandins can alter cervical consistency; however, it is clear that prelabor uterine activity plays a major role in cervical dilatation and effacement. Uterine contractions initially cause progressive effacement, then later dilatation of the cervix, as cervical tissue is pulled upward, over the presenting part, and is incorporated into the lower uterine segment. It is believed by many that

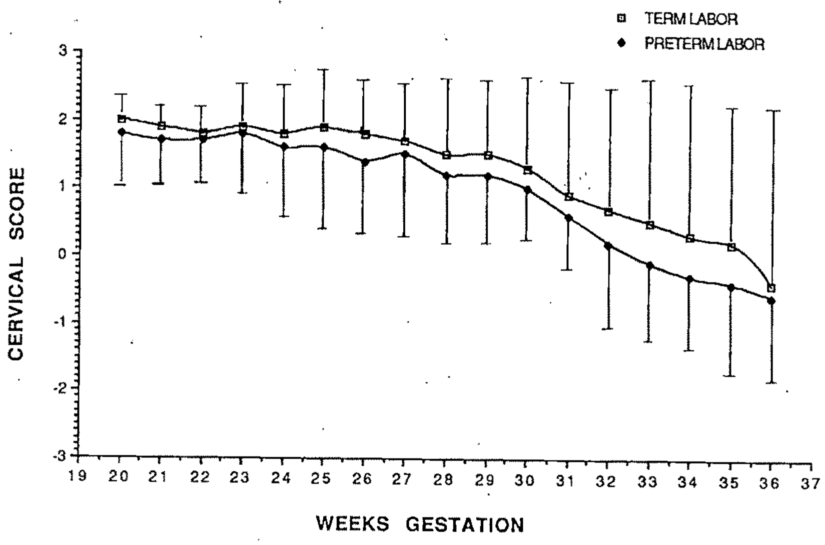

Fig. 3. Cervical score (mean ± SD) from 20 to 36 weeks' gestation for multifetal gestations with term (▫, $n = 34$) and preterm (♦, $n = 44$) delivery.

the frequency of these so-called Braxton Hicks contractions is related to the timing of the onset of labor.[7-9] The progressive fall in cervical score with advancing gestation appears to mirror the crescendo of prelabor uterine activity seen with multifetal gestations.[10]

The data presented suggest that information derived from a simple antepartum cervical examination can better define any patient's individual risk of preterm labor and delivery. Selecting a cervical score of ≤0 on or before 34 weeks' gestation as being abnormal was associated with a positive predictive value of 75% and a fourfold increased relative risk of preterm delivery. In the study of Neilson et al. a similar positive predictive value for preterm delivery was obtained with a cervical score of ≤ −2 or before 34 weeks' gestation.[2] It appears that in their population of parous African women a more advanced degree of cervical dilatation and effacement can be tolerated as compared with those of the patient population presented in this investigation.

We did identify that the earlier in gestation a cervical score of ≤0 is detected, the greater the positive predictive value that can be ascribed to it (i.e., 92% at 20 to 28 weeks' gestation). Parous women in this study tended to have lower mean cervical scores than did nulliparous women; however, this did not seem to significantly alter either the positive predictive value (72% vs 83%) or the relative risk (3.3 vs 4.3) of preterm delivery. As the cervical score becomes more negative at earlier gestational ages, the positive predictive value for preterm delivery approaches 100% but the sensitivity decreases because of the relative rarity of such abnormal antepartum cervical examinations. Obstetricians need complete knowledge of the evolution of cervical change in multifetal gestations to understand the prognostic significance of any specific cervical score.

Table II. Length of time from first appearance of specific cervical score to onset of labor

Cervical score	*No. of patients*	*Length of time to labor (wk, mean ± SD)*
+2.0	66	8.8 ± 4.2
+1.0	34	7.0 ± 3.5
+0.5	21	6.3 ± 2.9
0	25	3.7 ± 1.7
−0.5	18	3.9 ± 2.3
−1.0	26	3.2 ± 2.3
−2.0	14	2.0 ± 1.3
−3.0	12	1.5 ± 0.8

It seems most reasonable to use a cervical score of ≤0 as a marker of abnormal cervical status and increased preterm delivery risk. The first appearance of a cervical score ≤0 had the best correlation with the gestational age at delivery and provided the best sensitivity, specificity, and predictive values for preterm delivery. A cervical score of ≤0 seems to strike the correct balance between the number of women identified as being at increased risk of preterm delivery and the actual number of jeopardized babies correctly identified. The strength of the association between abnormal antepartum cervical scores and preterm delivery possibly may have been greater had it not been for the extensive use of tocolytic drugs. However, while these drugs delayed delivery for an average of almost 3 weeks, they allowed for the achievement of a term gestation in only four cases. Again, the similarity of our findings and those obtained by Neilson et al. in a pop-

Table III. Sensitivity, specificity, predictive values, and relative risk of premature delivery (<37 weeks' gestation) on basis of cervical score ≤0 on or before 34 weeks' gestation

Patient group	*Sensitivity*	*Specificity*	*Positive predictive value*	*Negative predictive value*	*Relative risk**	*p Value*
All patients	88%	62%	75%	81%	3.9 ($1.8<RR<8.7$)	≤0.0001
Patients 20-28 wk	33%	96%	92%	61%	2.0 ($1.4<RR<2.9$)	≤0.01
Patients 29-34 wk	87%	81%	73%	81%	3.8 ($1.7<RR<8.5$)	≤0.0001
Nulliparous	83%	75%	83%	75%	3.3 ($1.0<RR<11.4$)	≤0.02
Parous	91%	58%	72%	83%	4.3 ($1.5<RR<12.4$)	≤0.001

**RR*, Relative risk (with 95% confidence limits).

ulation not exposed to tocolytic therapy suggests a relatively insignificant role for these agents.

Of particular interest is the fact that only two women experienced spontaneous preterm labor or preterm premature rupture of the membranes within 1 week of having a cervical score >0. In the series of Neilson et al.[2] of 223 twins, none were delivered within a week of a cervical score ≥0. Women who can maintain a cervical score of >0 would seem to be good candidates for continued conservative observation rather than being subjected to any of the controversial obstetric interventions available to us. Several studies have failed to demonstrate any advantage to routine hospitalization and bed rest for either twin[11, 12] or triplet[13] gestations. Also called into question is the value of any degree of activity restriction in multifetal gestations short of hospitalization and bed rest. The routine use of prophylactic tocolytic therapy has not been clearly shown to be effective despite extensive use.[14, 15] Home uterine activity monitoring has been effective in making the early diagnosis of preterm labor in multifetal gestations but remains an expensive and labor-intensive approach to preterm birth prevention.[13, 16, 17] The differentiation of normal from abnormal cervical scores may be of value in designing clinical protocols or trials to determine the indications for and effectiveness of these obstretric interventions.

The cervical score was selected for evaluation because of its simplicity, quantifiability, reproducibility and focus on cervical dilatation and effacement. Among singleton gestations, changes in cervical dilatation and effacement are the best predictors of prematurity.[18-20] The previously described work of both Neilson et al. and Houlton et al. suggests that the cervical score has good prognostic value in multifetal gestations.[1, 2] At our own institution we have documented that interexaminer differences in the assessment of cervical dilatation and effacement are small, which suggests that the human hand is a sensitive instrument for examining these properties of the cervix.[18] The ability to quantify the cervical score allows for better communication between examiners and helps to eliminate subjective bias. Evaluations of cervical position and consistency are subjective by their very nature and provide little prognostic information once dilatation and effacement have been considered.[20] The station of the presenting part is significantly affected by parity, as well as by malpresentation, which is not uncommon in multifetal gestations.[1]

A final consideration is the safety of the antepartum cervical examination. Lenihan[21] has demonstrated increased risk of premature rupture of the membranes in women undergoing weekly cervical examination after 37 weeks' gestation. Bacterial colonization of the endocervix has been reported to be both increased and unchanged in patients with premature rupture of the membranes.[22, 23] However, no one has yet evaluated whether the antepartum cervical examination alters the endocervical flora.

Holbrook et al.[24] evaluated the role of the cervical examination as a component of the San Francisco preterm birth prevention program. On comparison with a large control group who did not receive antepartum cervical examination, there was no increase in rates of premature rupture of the membranes, chorioamnionitis, or endometritis, nor was there any relationship between the date of the last cervical examination and the ultimate onset of premature labor. Main et al.[25] described an inner-city population where the rates of premature rupture of the membranes were very high in a group of women who had routine antepartum cervical examinations, but the rate was also excessive among a high-risk control group who were not examined. Most important, successful local and regional programs preventing premature birth have all emphasized antepartum cervical examination.[26-28] The results of these investigations would make it seem unlikely that routine antepartum cervical examination is having any significant effect on rates of either spontaneous premature labor or preterm premature rupture of the membranes. In this study our rate of preterm premature rupture of the membranes was 15%, which is consistent with the rates reported in other reviews of multifetal gestations not having routine cervical examination.[29, 30]

Antepartum cervical examination in multifetal gestations for the calculation of a cervical score seems to be a safe, easily obtained, and valuable technique in refining our ability to predict the risk of preterm delivery. An understanding of the prognostic significance of specific quantifiable cervical data may be of great value in determining the need for obstetric intervention in multifetal gestations.

Discussion

DR. JOHN B. WILLEY, Winchester, Virginia (Official Guest). When given the opportunity to prepare this review, I began looking for the earliest reference to the delivery of premature twins and I think I found it. From Genesis 25:24 and 25 we learn, "When her days to be delivered were fulfilled, behold, there were twins in her womb. The first came forth red, all his body like a hairy mantle; so they called his name Esau."

This to me is a fairly typical premature twin with the scalded appearance ("red" in the passage) and lanugo ("hairy mantle") that we have all come to recognize. We have no record of Rebekah's prenatal vaginal examinations.

Since Bishop[1] first looked to cervical evaluation for consideration of induction of labor, we have been made aware not only of the impression given by the vaginal examination but also of the quantification of such an examination. Recent studies such as that of Newman et al. have quite rightly deemphasized the more subjective elements of Bishop's score (consistency, station, and position) and concentrated on the more quantifiable cervical score obtained by subtraction of dilatation from effacement.

This study helped me to think more concretely about the importance of examination of preterm cervix. The data, while not falling as neatly as we might hope into categories of "at risk" and "not at risk," are impressive in several points. The relatively low risk for the patient with a cervical score >0 is helpful clinically. The increasing importance of a score <0 and the importance of its determination early in pregnancy, while intuitively apparent, are well documented here. The possibility that we can identify 73% of those twin gestations at risk of premature labor by a single examination before 34 weeks is intriguing.

One question I have concerning the study pertains to the reliability of multiple examiners to give like scores to one cervix. In spite of the authors' allusion to the small interexaminer differences in cervical assessment,[2] I remain somewhat skeptical. In my own hospital, where labor and delivery nurses perform many cervical examinations, I am often confronted with the differences between the examinations from nurse to nurse and from physician to physician. When I ask the nurse to tell me a patient's status, and she says, "Dr. X says she is 5 cm," both of us know that Dr. X's 5 and my 3 are equivalent. One of the strengths of the data in the work of Nielson et al.[3] from Zimbabwe, referred to in this article, is that all examinations were done by one of the two coauthors. A stronger case might be made if all examinations were done by one examiner, but I realize that the logistic problems of such a restriction are many.

A second question about this study is a fundamental problem with many medical surveys, that is, the need to react to the parameter under surveillance and thereby cloud the issue under study. One rather nice thing about the Zimbabwe article was that the data were unchanged by intervention and perhaps were more valid for that reason. The fact that tocolysis was so rare in the Zimbabwe study is a plus for that set of data that Dr. Newman and coworkers could not ethically achieve. I would like to know, in addition, what was done to each of these patients when a cervical change was documented. Such a discovery surely led to manipulations such as rest, tocolysis, and perhaps even cerclage or pessary use that hopefully would have altered the course of labor or prelabor cervical change and therefore affected the evolution of the cervical score. It is certainly possible to interpret the data as more valid because of these manipulations. As the authors pointed out, the association between abnormal antepartum cervical scores and preterm delivery may have been greater had it not been for the extensive use of tocolytic drugs.

Finally, I am troubled by the repeated vaginal examinations. Without a study to back me up, I believe that I noticed a decrease in amnionitis and postpartum endometritis after I left my residency. A great deal of that may be related to the fact that teaching hospitals care for sicker patients who require more intervention. In spite of that I believe some percentage of these infections come from the multiple examinations by multiple examiners that are part of care in teaching institutions. The work of Lenihan[4] concerning prelabor cervical examinations and premature rupture of the membranes had some far-reaching effects in our practices. In my office we have stopped routine weekly assessment by vaginal examination from 36 weeks because of that study. Should we then examine weekly, from much earlier on, the very patients believed to be more likely at risk of premature rupture of the membranes and amnionitis? Fifty-six percent of the study patients had preterm delivery. Does this represent an improvement over the preterm delivery rate expected, and if not, could infection play a part?

In this regard it would be good to know exactly how these examinations were done. Are the patients prepped for a sterile vaginal examination, as we were taught in our residencies, or are they examined with a sterile glove and K-Y brand lubricating jelly or perhaps Betadine povidone-iodine gel? Were all examinations conducted the same way? Was each examination an intracervical one or are paracervical examination and visual inspection sufficient and less risky?

The interest of Newman et al.[5] in premature labor, the influence of fetal number on premature labor,[6] and the management of multiple pregnancy[7] are well documented in the literature. It has been a pleasure to consider in more detail the entire topic. I want to thank the authors for their continuing efforts to quantify the risk and help us with management of this difficult obstetric problem.

DR. JOHN W.C. JOHNSON, Jacksonville, Florida. I want to congratulate the authors on what I think is a very interesting study. This looks like a simple way to identify patients at high risk. I wondered if they have compared their approach to home monitoring, and could Dr. Newman give us some information about the relationships and interactions of these two methods of monitoring?

Dr. Leslie W. Beadling, Jacksonville, Florida (Official Guest). I was wondering if the authors have considered using ultrasonography, rather than doing vaginal examinations, to arrive at cervical scores?

Dr. Ernest H. Brown, Jr., Lumberton, North Carolina. With scores of ≤0 were cervical cultures done and were antibiotics considered in management?

Dr. Henry R. Temple, Wilmington, North Carolina. I would like Dr. Newman to comment on the five elective preterm deliveries and how these affect the overall results, if they are eliminated from the study.

Dr. Newman (Closing). The elective preterm deliveries were excluded from the analysis; therefore they have no impact on the results we presented. We did not do cervical cultures on the patients found to have advanced cervical change. This is a good suggestion and something we need to consider. One of our interests had been to perform cervical cultures to see if the antepartum cervical examination changes the bacteriologic milieu. This will be done in the future.

The use of ultrasonography for the evaluation of the cervix is intriguing. We did not have this capability in our clinic because of a lack of a vaginal probe. A word of caution is warranted in that the vaginal probe examination requires the blind introduction of a rigid and blunt instrument into the vagina. Because of manual dexterity, a digital examination actually might be a safer procedure.

We have not related our cervical change information to home uterine activity monitoring. The vast majority of the patients in this study were not performing home uterine activity monitoring. We hope to study the natural history of cervical change simultaneously with changes in uterine activity. The graph that shows the fall in cervical score with advancing gestation probably could be superimposed inversely on a graph showing increased baseline uterine activity in multiple gestations. The cervical score may prove to be useful in identifying women who are candidates for home uterine activity monitoring for the identification of increased uterine activity and more effective suppression of that activity.

With respect to the reliability of multiple examinations, I have referenced work by Stubbs et al.[1] from our own institution in which two different examiners in our antepartum clinics demonstrated good correlation in their assessment of cervical dilatation and effacement. Ninety percent of the time there was a difference of <1 cm in their measurement of cervical dilatation and in only 2% of >350 paired examinations was there a difference in dilatation of >1 cm. In only 7% of the paired examinations was there as much as 1 cm difference in cervical length. Stubbs et al. concluded that the hand is a very reliable and sensitive instrument for cervical examinations. The issue regarding tocolytic therapy for multiple gestations is significant and needs to be answered. When we do identify an abnormal cervical score, we use betamethasone prophylactically for the enhancement of fetal lung maturation. We also use the cervical score as a guideline for determining the extent of activity restriction and bed rest. A patient with a fall in cervical score from one week to the next is frequently sent to our labor and delivery unit for monitoring of possible preterm labor.

The risk of the antepartum cervical examination has been addressed in the literature by Lenihan.[2] It is important to note that his examinations were performed after 36 weeks' gestation, and I suspect they were performed in an effort to induce labor by the stripping of membranes. The preponderance of evidence suggests no adverse outcome as a result of a gentle antepartum cervical examination. I would add that the successful preterm birth prevention programs reported by Papiernik et al.[3] in France, Meis et al.[4] in North Carolina, and Herron et al.[5] in California all used antepartum cervical examinations. In their reports, albeit on singleton gestations, they showed no increase in the risk of premature delivery. In fact, they showed a reduction in the preterm delivery rates. In performing our examinations, we did not prep our patients. The examinations were performed with sterile gloves and K-Y brand lubricating jelly. At our institution we do an internal cervical examination as opposed to examining only the outside of the cervix. The examining finger is not passed beyond the point at which some resistance is identified.

Can the same information be gained by examining the external cervical os? I am not sure. Cervical effacement is evaluated by examining the outside of the cervix. However, I don't believe you can determine cervical dilatation by examining only the external portion of the cervix.

Appropriateness of intrapartum fetal heart rate management and risk of cerebral palsy

Paula J. Melone, DO, J.M. Ernest, MD, Michael D. O'Shea, Jr., MD, and Kurt L. Klinepeter, MD

Winston-Salem, North Carolina

Cerebral palsy affects 2 in 1000 infants in the United States, and the intrapartum period is frequently scrutinized as the etiologic source. In a matched group of 49 infants with cerebral palsy at 1 year of age and 49 controls, no difference in the incidence of inappropriate intrapartum fetal heart rate pattern management was detected. This supports the conclusions of others that the intrapartum period is an infrequent source of cerebral palsy. (AM J OBSTET GYNECOL 1991;165:272-7.)

Key words: Cerebral palsy, fetal heart rate patterns, intrapartum management

Cerebral palsy is an infrequent event affecting 2 in 1000 infants in the United States.[1] Studies from the United States of births in the 1950s and 1960s[2] and from Australia of births in the 1970s and 1980s[3] investigating antecedents of cerebral palsy concluded that most cases have no identifiable antecedent events during the intrapartum period. Other studies[4, 5] have shown slight or no reduction in cerebral palsy rates after the advent of electronic fetal monitoring, which also suggests that intrapartum events are infrequent causes of cerebral palsy. In reviewing the prenatal and intrapartum courses of 34 infants in whom cerebral palsy developed, Niswander et al.[6] found no association between substandard obstetric care or delayed reaction to apparent intrapartum asphyxia and the development of cerebral palsy.

In spite of mounting evidence that cerebral palsy is rarely associated with or caused by intrapartum events, including the management of various patterns of the fetal heart rate (FHR), the intrapartum time period continues to be scrutinized as the likely source of many cases of cerebral palsy. This belief implies that appropriate intrapartum management of the FHR and its various patterns should rarely be associated with cerebral palsy.

Because of concerns regarding the quality of intrapartum care and resultant cerebral palsy, we asked the following question: Do babies in whom cerebral palsy develops have a higher incidence of inappropriate intrapartum management of nonreassuring FHR patterns than babies in whom cerebral palsy does not develop?

Material and methods

A blind, retrospective review of intrapartum management and fetal monitor strips was conducted by two perinatologists (P.J.M. and J.M.E.) for 50 infants with a diagnosis of cerebral palsy at 1 year of age and 50 matched controls. The 100 infants studied were born between 1983 and 1989 at Forsyth Memorial Hospital in Winston-Salem, North Carolina. All study infants with cerebral palsy were chosen from a group of newborns who required neonatal intensive care and who were examined at 1 year of age by one author (K.L.K.). The diagnosis of cerebral palsy was based on the finding of a motor impairment, independent of other developmental impairments. Abnormalities of position and posture were ascertained during independent evaluations by a developmental pediatrician and a pediatric physical therapist. These evaluations occurred on the same clinic date. Occasionally, serial clinic evaluations over the first year of life were required to firmly establish the diagnosis of cerebral palsy. Abnormal tone was the predominant clinical finding. Involuntary movements were not observed because of the age of the children at diagnosis. A control infant was matched for each study infant by review of obstetric delivery logs and choosing the next newborn with matching maternal race, gestational age within 1 week, and birth weight within 225 gm. Only singleton pregnancies were reviewed. The presence of specific antepartum and intrapartum factors related to cerebral palsy[2] also was evaluated. The two perinatologists, who were blind to the subject's status as a case or control, independently reviewed the intrapartum management and fetal monitor strip of each newborn and determined if specific nonreassuring FHR patterns were present and whether management was appropriate or inappropriate. If

6/6/30394

there was a discrepancy in their assessment of the appropriateness of care, the tracings were then reviewed by the perinatologists together, still blind as to whether the infant was a case or control newborn, to arrive at a consensus about appropriateness of care. All fetal monitor strips from each infant were reviewed, but only the 24 hours immediately preceding delivery was considered in the evaluations.

A FHR tracing was considered nonreassuring when one or more of the following was present: (1) prolonged bradycardia, defined as >2 minutes of FHR <90 beats/min; (2) recurrent late decelerations, defined as >1 hour of late decelerations in >50% of contractions in the absence of uterine hypertonicity; (3) severe variable decelerations, defined as >20 severe variable decelerations (<60 beats/min for >60 seconds' duration or >60 beats/min drop from baseline) during the course of labor.

Appropriateness of care was modified from Niswander et al.[6] No intervention was considered necessary in the intrapartum period when the following occurred: presence of reassuring FHR tracing with FHR accelerations and normal short-term beat-to-beat variability or presence of mild variable decelerations, <1 hour of late decelerations, <20 severe variable decelerations, or bradycardia to 90 beats/min for <2 minutes, as well as absence of the nonreassuring patterns previously described.

Appropriate management for nonreassuring FHR tracings was considered as follows: severe variable decelerations >1 hour or late decelerations >1 hour in >50% of contractions—maternal oxygenation and repositioning, discontinuation of oxytocin augmentation when present, fetal scalp blood pH testing if decelerations persisted in spite of interventions, and prompt delivery if the nonreassuring pattern did not subside, particularly if short-term beat-to-beat variability was absent with a fetal scalp blood pH <7.20 or if no pH was attainable and delivery was not imminent. The management of thick meconium was considered appropriate if a scalp electrode was placed, oxygen was given with a nonreassuring FHR tracing, and the above-described scheme was followed in the event of a nonreassuring tracing.

Inappropriate management was considered to have occurred when a deviation from the above recommendations occurred with a nonreassuring FHR tracing.

The electronic fetal monitor strip of one infant with cerebral palsy was misplaced during the study, and that pair was removed from final analysis. Of the 49 remaining infants in each group, five infants in the cerebral palsy group and three in the control group had a rapid admission-to-delivery interval of <60 minutes ($n = 5$) with no electronic fetal monitoring, had a scheduled repeat cesarean section ($n = 1$) with no electronic fetal monitoring, had <30 minutes of electronic fetal monitoring before emergency cesarean section ($n = 1$), or was delivered by an emergency cesarean section on hospital day 6 with no electronic fetal monitoring after two previous days of normal FHR pattern by electronic fetal monitoring ($n = 1$). In these eight infants only the presence of bradycardia and variable decelerations as documented by nursing or physician attendants was reported, because late decelerations cannot easily be detected by auscultation or a brief electronic fetal monitoring period as in these eight infants. In all 98 remaining cases nursing notes and intrapartum records were available for review.

Statistical analysis was done with Student's *t* test and χ^2 test or Fisher's exact test (one-tailed) where appropriate.

Results

Table I presents the population characteristics of the 98 infants. No statistically significant differences were noted in the mean maternal age, race, gravidity, mean gestational age at birth, or mean birth weight. Antenatal and intrapartum factors associated with cerebral palsy were found in equal frequencies in both groups. Table II gives delivery characteristics of the two groups. There was a statistically significant difference in the Apgar scores at 5 minutes ($p < 0.04$) but not at 1 minute. In 27 infants in the cerebral palsy group and 21 infants in the control group, umbilical cord blood gas values were available for review. Although 22% of the cerebral palsy group had umbilical arterial pH levels <7.20 versus 5% in the controls, the difference was not significantly different in these small groups. More newborns with cerebral palsy than control newborns also had umbilical vein pH levels <7.20 (18% vs 0%), and this difference was statistically significant ($p < 0.05$).

Nonreassuring FHR tracings occurred in 35% of the control infants and 31% of the cerebral palsy infants. Table III shows the occurrence of various nonreassuring FHR patterns and the number of patients with inappropriate intrapartum management. Similar results in Table II (delivery characteristics) and Table III (intrapartum FHR patterns and management) were seen when the eight patients with no or inadequate electronic fetal monitoring strips and their matched infants were excluded from the analysis.

Comment

Since 1862, when orthopedist William Little[7] proposed that the origins of cerebral palsy were in the circumstances of birth, many have believed that most cases of cerebral palsy arise from intrapartum events. The logical correlate to this belief is that improved intrapartum care would greatly reduce the incidence of

Table I. Population characteristics

*>5 gm/24 hours or 4+ on single voided specimen.

cerebral palsy. Unfortunately, many studies have failed to support these notions.

Nelson and Ellenberg[2] in the Collaborative Perinatal Project of the United States and Blair and Stanley[3] in Western Australia showed remarkably similar rates of cerebral palsy (<10%) when adverse intrapartum events or intrapartum asphyxia was the only obvious risk factor. In another analysis of the Collaborative Perinatal Project data, Naeye et al.[8] reported that birth asphyxia accounted for only 6% of the cerebral palsy cases in the Collaborative Perinatal Project study as a whole. Most cases of cerebral palsy in these reports appeared to originate either prenatally or postnatally.

Reviews of trends of the incidence of cerebral palsy before and after the advent of electronic fetal monitoring also have failed to demonstrate the dramatically falling rates of cerebral palsy that were originally predicted. In Western Australia rates of cerebral palsy were remarkably stable before and after electronic fetal monitoring was utilized.[9] In Sweden[5] rates of cerebral palsy actually increased slightly. Only in the United States, in a report from Wisconsin,[1] has the incidence of cerebral palsy decreased after the institution of intrapartum electonic fetal monitoring. This decrease in cerebral palsy incidence was limited to the neonate with a birth weight >2500 gm.

Other studies also suggest a lack of association between intrapartum events and the occurrence of cerebral palsy. Nelson and Ellenberg[10] reported in 1981 that 75% of term infants with cerebral palsy had 5-minute Apgar scores of ≥7. Painter et al.[11] followed the neurologic development of a group of children with abnormal FHR decelerations during labor and found all infants without genetic syndromes to be normal at age 6 to 9 years. Severe acidosis at birth in appropriate-for-gestational-age term infants in The Netherlands was not found to be a major cause or predictor of later neurologic abnormalities.[12] Even studies by Myers,[13] in monkeys in which acute hypoxia was induced, failed to consistently produce a clinical picture like cerebral palsy.

In this study the intrapartum courses and FHR patterns of 49 infants with cerebral palsy diagnosed at 1 year of age and 49 matched controls were reviewed and reported. Similar rates of nonreassuring FHR patterns as defined in this study were seen in both groups. Interestingly, more of the control infants had evidence of inappropriate FHR management during labor than did infants who later showed evidence of cerebral palsy (16% vs 10%, p not significant). This similar occurrence rate of nonreassuring intrapartum FHR patterns in both groups of infants is consistent with numerous other reports implying a prenatal (but not intrapartum) etiologic source of cerebral palsy in most cases. The only intrapartum FHR pattern in this study showing a possible trend toward association with subsequent cerebral palsy was bradycardia ($p = 0.059$), which has been reported in earlier studies.[2]

In this study significantly more 5-minute Apgar scores ≤6 were seen in the cerebral palsy group than in the control group. Also more babies with cerebral palsy had umbilical arterial or venous pH levels <7.20, although these differences were statistically significant only for the venous pH results. No difference was seen in the 1-minute Apgar scores. Because the gestational ages were matched and similar resuscitation methods were used for all babies in need, the lower 5-minute scores may reflect simply the increased incidence of acidosis in the babies that ultimately were diagnosed as having cerebral palsy. The trend toward more acidosis in babies in the cerebral palsy group may reflect our present inability to diagnose all intrapartum fetal aci-

Table II. Delivery characteristics

dosis with electronic fetal monitoring, especially if cerebral acidosis is not present. Others have shown that even severe acidosis at birth is a poor predictor of subsequent neurologic dysfunction.[14]

Although this report includes the largest series of infants studied to date for appropriateness of intrapartum FHR management and development of cerebral palsy, potential weaknesses exist.

One potential weakness is the choice of FHR patterns defined as nonreassuring, as well as the relatively short duration used in the definition. In a randomized study comparing electronic FHR monitoring to intermittent auscultation in a group of premature infants,[15] the risk of cerebral palsy was increased as the duration of the abnormal FHR pattern increased in the electronically monitored group. Had the nonreassuring FHR changes been defined differently or taken place over a longer period of time than defined in this study (for example, late decelerations for >1 hour), more evidence of fetal damage may have occurred. The time frames used were arbitrary attempts to define a reasonable period of time in which most physicians would act rather than a delimiting time in which damage does occur. A second potential weakness of the study is the relatively small number of cases and controls used. When no difference between two groups is shown, caution must be taken to prevent a type II error—not recognizing that a true difference exists between groups because of the small sample size. The prevalence of cerebral palsy is 0.2% in all births and approximately 4% in births <2500 gm.[1-9] Assuming a 4% incidence of cerebral palsy in this population with mean birth weight <2500 gm and assuming inappropriate FHR intrapartum management results in ≥50% of cases of cerebral palsy, the power of this study is >99%. However, if inappropriate intrapartum managment as defined in this study is assumed to result in only a 10% rate of cerebral palsy, the power is reduced to only 12%. To detect a difference of this magnitude with a power of 80% would require 603 pairs of infants.

This study does not imply that intrapartum FHR managment is unimportant or may not possibly lead to fetal damage in some cases. Several studies have demonstrated that, with a clearly asphyxiated newborn, damage may occur.[10, 16-18] Rather, this study suggests that most infants who survive neonatal intensive care and develop cerebral palsy have appropriately managed intrapartum FHR patterns and that inappropriate intrapartum FHR management occurs with equal frequency in infants in whom cerebral palsy develops and in normal newborns. Whereas we should continue to improve our intrapartum FHR management skills, we should remember that even the most skilled intrapartum care may not prevent the development of most cases of cerebral palsy.

Discussion

DR. ALEXANDER R. SMYTHE II, Columbia, South Carolina (Official Guest). This article touches on one of the most sensitive questions the obstetrician faces in today's medical-legal climate. Does the intrapartum period cause brain-damaged infants and cerebral palsy, or can it be absolved of blame?

This study attempts to take a small number of patients over a period of 6 years, compared with controls, and look at a nebulous question of whether inappropriate obstetric management had an influence on the incidence of cerebral palsy.

The results of this study showed no increase in cerebral palsy in patients who were deemed to be inappropriately managed in the control group and the group in whom cerebral palsy developed by definition. The incidence of cerebral palsy is small, 0.2% of all live births, and reported to be 4% in infants <2500 gm. Consequently, it would take a study of the magnitude that the authors have mentioned, somewhere on the order of 500 to 1000 patients born with cerebral palsy, to establish some cause-and-effect relationship.

The incidence of cerebral palsy has plateaued in the last 20 years with a decrease in birth trauma because of difficult operative vaginal deliveries. The mark of a good obstetrician used to be his ability to deliver an infant in the face of the most difficult vaginal circumstances. This study reminds me of the article by Schifrin and Dane[1] where they attempted to predict Apgar scores by reviewing FHR monitoring strips 30 minutes before delivery. Their study revealed two pertinent points. If the FHR monitor strip looked absolutely normal and reassuring, it had a very high index of predictability of a good Apgar score. If the FHR strip was very unreassuring and a poor Apgar score was predicted, only 20% of patients predicted to have a poor score did so, but all of the infants born with poor Apgar scores were included in this group. Consequently, the diagnosis of fetal distress was overdiagnosed in many cases in infants who were born in good health.

If we could appropriately manage even the 12% of patients in this study in whom cerebral palsy developed, we might reduce the current incidence of cerebral palsy by a fractional amount. If we assume for a moment that labor lasts 24 hours and a normal gestation is 270 days, we are looking at a small amount of time in a newborn infant's span (0.36%). This is a small blip on the continuum of life, and many studies mentioned by the authors and others have concluded that 90% of cerebral palsy is prenatal or postnatal and only 6% to 10% can be attributed to intrapartum events.

Genetic and chromosomal factors, prematurity, multiple pregnancy, hypertensive proteinuria, anomalies, bleeding disorders during pregnancy, and prenatal infections account for the majority of cases of cerebral palsy. We, as obstetricians, need to continue to improve our prevention and treatment of preterm labor, chorioamnionitis, neonatal sepsis, and seizures to reduce the incidence of cerebral palsy from an obstetric and pediatric standpoint. Prematurity with its incidence of intraventricular hemorrhage is responsible for a large percentage of patients in whose infants cerebral palsy develops.

This is reflected in the authors' study by a mean gestational age of 29.9 weeks and a mean birth weight of 1530 gm. This study also reveals the fact, once again, that cesarean section does not protect against the development of cerebral palsy and should not be used in preterm deliveries unless obstetric guidelines dictate.

An excellent study by Grant et al.[2] presented at the World Perinatal Symposium and published in *The Lancet* in 1989 involved a randomized trial of 13,079 liveborn children. Electronic fetal monitoring was compared to intermittent auscultation to determine if fetal monitoring had any protective effect against cerebral palsy.

There was no difference between the groups in the overall death rate, but neonatal seizures were found significantly less often in the monitored group. Again, this study indicated that suboptimal intrapartum care (in particular, failure to respond appropriately during labor to an abnormal FHR pattern) was shown to be associated with about a threefold increase in the risk of very early neonatal seizures but not with an increased risk of cerebral palsy.

Again, I would like to commend the authors on an excellent study showing that even inappropriate responsiveness to FHR abnormalities as defined by them failed to cause an increase in the incidence of cerebral palsy. This is an important topic and will continue to bewilder the legal and medical field until we can understand and study in utero the developing fetus to a much closer degree.

2. Grant A, O'Brien N, Joy M-T, et al. Cerebral palsy among children born during the Dublin randomised trial of intrapartum monitoring. Lancet 1989;2:1233.

Dr. Charles J. Ward, Decatur, Georgia. I commend the physicians on this study. It will be very helpful not only for our profession but for those who enter the legal arena to defend physicians in cases of cerebral palsy. I would ask if the placenta was retained in any of the cases? We have learned that an abnormal proliferation of trophoblasts in the spiral arteries at about 16 to 18 weeks of gestation reduces the flow to the intervillous space and is associated with villous edema. Were the placentas saved in any of these cases and, if so, are they still available for study?

Dr. Mason C. Andrews, Norfolk, Virginia. Dr. Smythe pointed out the importance of prematurity in this condition. The study is reassuring about our obstetric care. I wonder if the authors could tell us how many of the 50 cases had intraventricular hemorrhage?

Dr. Ernest (Closing). I think it is appropriate to remember that labor involves only 0.36% of an entire gestation. People wonder whether cerebral palsy is related to labor or to the process of prelabor, which is much longer. It is reassuring that Grant et al. reported that neonatal seizures, while frightening, usually do not correlate with subsequent neurologic damage.

The placentas were not retained. As things evolve and as we learn more, I believe that when we deliver a baby that "looks funny," has meconium in the amniotic fluid, or is preterm, we ought to at least evaluate umbilical cord blood gas values and probably send the placenta for pathologic examination so that we can save it and look at it later if the case "comes back to haunt us" in court.

I do not know the number of babies who had intraventricular hemorrhage, but I think it is also an important consideration.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $34.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Resolution of chronic pelvic pain after laparoscopic lysis of adhesions

John F. Steege, MD, and Anna L. Stout, PhD
Durham, North Carolina

Thirty women undergoing laparoscopic lysis of adhesions for the treatment of chronic pelvic pain were prospectively evaluated for the presence of a chronic pain syndrome. At follow-up, of those with chronic pain syndrome (10), four (40%) reported continued improvement or resolution of pain during daily activities or dyspareunia, whereas of those without chronic pain syndrome (20), 15 (75%) were better ($p = 0.06$). When these two complaints are evaluated individually, both pain during daily activities ($p < 0.05$) and dyspareunia ($p < 0.05$) are more likely to improve after lysis of adhesions in women without chronic pain syndrome. Prognosis was not related to the number of previous operations, adhesion score, or other physical parameters. Laparoscopic lysis of adhesions is generally worthwhile in the treatment of chronic pelvic pain, although the presence of psychosocial compromise warrants preoperative evaluation and concomitant treatment. (AM J OBSTET GYNECOL 1991;165:278-83.)

Key words: Chronic pelvic pain, adhesions, operative laparoscopy

Of all operative laparoscopy procedures performed in the United States, about 40% are done for the evaluation and treatment of pelvic pain.[1] In approximately 30% to 50% of chronic pain cases, pelvic adhesions are found,[2-4] although their relationship to pain is uncertain.[5, 6] We recently reported that the location of pain correlates well with the location of the pathologic condition (usually adhesions or endometriosis),[7] although the available clinical studies do not demonstrate a quantitative relationship between adhesions and chronic pelvic pain.[7, 8]

Studies of other chronic pain problems such as low back pain have similarly failed in the attempt to quantitatively associate pain with a pathologic condition.[9] Together with other observations,[10] these studies point out the inadequacies of the Cartesian theory of pain perception, which hypothesizes unique pain fibers and holds that pain is proportional to tissue damage. Newer theories of pain perception such as the gate control theory and cognitive models include the influences of culture, psychologic conditioning, cognitions, affect, and stress.[11] Considering these complexities, it should perhaps not be surprising that attempts to find enough pathologic conditions to explain chronic clinical pain have routinely been frustrating. Clearly, some patients get negative or nociceptive input of substantial degree from their illnesses but never develop the affective, behavioral, and cognitive hallmarks of what we have called a chronic pain syndrome.[12] When these behavioral and psychologic changes do occur, to what degree is it useful to treat conditions, such as pelvic adhesions, that rarely affect general physical health?

This study of laparoscopic lysis of adhesions assesses outcome in terms of relief of daily pain and dyspareunia and examines the relationship between pain relief and the preoperative diagnosis of a chronic pain syndrome.

Methods

Thirty-four women aged 18 to 70 years (mean, 34.9 ± 9.9 years) were evaluated in a teritiary care medical center for chronic, constant pelvic pain of ≥6 months' duration. Consecutive patients who ultimately proved to have pelvic adhesions at laparoscopy were included in the present study. All women submitted documentation of previous medical care, including surgical procedures, and completed detailed clinical interviews and physical examinations. Of the 30 women reached for follow-up evaluation, one had previously had unilateral salpingo-oophorectomy, whereas 19 had undergone hysterectomy, 10 with bilateral and five with unilateral salpingo-oophorectomy.

At their first visit patients rated dysmenorrhea, dyspareunia, and pain during daily activities on a numerical scale of 0 to 10, with the anchors of 0 being "no pain" and 1 being the "worst pain I can imagine." The following parameters of the pain were then scored by the clinician as present or absent: (1) pain duration of ≥6 months, (2) incomplete relief by previous treatments (e.g., analgesics, prior operations), (3) impaired

†$p < 0.05$, combining all nonimproved categories.
‡$p = 0.06$.

physical function (work, recreation, etc.), (4) at least one vegetative sign of depression (sleep disturbance aside from being awakened by pain, loss of appetite, or psychomotor retardation), and (5) altered family roles. The last category included child care and household responsibilities, financial decision making, and emotional involvement with and support of other family members. Women were designated as having a chronic pain syndrome if four or more of these characteristics were present.

All the women underwent operative video laparoscopy while they were under general anesthesia, using a carbon dioxide laser, scissors, hydrodissection, and blunt dissection to lyse adhesions. At the termination of each procedure, Interceed (Johnson & Johnson, Newark, N.J.) adhesion barrier was placed over areas of dissection along the pelvic sidewalls and moistened with 4 to 6 ml of heparin, 1000 U/ml. Patients returned for follow-up examinations at 1 month and again at intervals ranging from 6 to 12 months (mean, 8.2). At follow-up all patients either scored pain during a structured clinical interview or completed a questionnaire including the same rating scale items.

Before tabulation of the clinical data on pain severity and chronic pain syndrome classification, all videotapes of the laparoscopic procedures were reviewed and adhesions were scored in the following areas: (1) right ovary, (2) right tube, (3) left ovary, (4) left tube, (5) omentum, (6) large bowel, (7) small bowel, (8) pelvic sidewalls, and (9) cul-de-sac. The severity of adhesions was rated as follows: 0, none; 1, filmy; 2, dense or vascular; and 3, dense and vascular. Dense was defined as opaque, and vascular as bleeding on laser dissection or, in the judgment of the operator, necessitating electrocoagulation before severing with scissors or laser. A total adhesion score was then calculated by summing scores across all nine areas evaluated. Adhesion location was compared with pain location, with reported pain characterized as right, left, central, or any combination of these areas.

Patients were then categorized by the presence or absence of chronic pain syndrome, and the resulting two groups were compared across demographic variables, adhesion scores, and clinical outcome at 6 to 12 months (mean, 8.2) after surgery. Categoric variables were compared with the χ^2 test or Fisher's exact statistic and continuous variables with the Student t test and Pearson's r; $p < 0.05$ was used as the level of significance.

Results

Ten patients had a chronic pain syndrome and 20 patients did not. By virtue of the inclusion criteria for the study, all patients fulfilled the first two criteria for a chronic pain syndrome (duration of ≥6 months, incomplete relief by previous treatments). In addition, 19 had impaired physical function, nine had at least one vegetative sign of depression, and seven acknowledged significant changes in their roles within the family.

Of the 30 patients completing evaluation, 25 had had laparotomy (mean ± SD, 1.55 ± 1.27; range, 1 to 4),

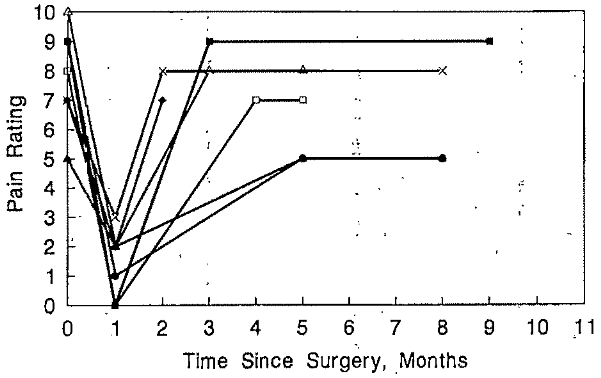

Fig. 1. Time of return of pain during daily activities after laparoscopic lysis of adhesions (n = 8).

and 10 had had laparoscopy (mean ± SD, 0.52 ± 0.83; range, 1 to 3). Patients with chronic pain syndrome more often had prior operations (laparotomy, 1.9 vs 1.36; laparoscopy, 0.8 vs 0.36) and hysterectomy (80% vs 55%), but neither of these differences reached statistical significance in this sample. Patients with and without chronic pain syndrome had similar preoperative ratings of dyspareunia and pain during daily activities, as well as similar adhesion scores (Table I). Because of the paucity of women with chronic pain syndrome and intact uteri (n = 2), the effects of laparoscopic lysis of adhesions on dysmenorrhea could not be compared between the two groups.

Pain location overlapped with the location of adhesions in 90% of patients; both were scored by dividing the pelvis in thirds (right, left, and middle). Preoperative ratings of dyspareunia and pain during daily activities did not correlate with adhesion scores in the study as a whole or in the patients with or without chronic pain syndrome. Small- or large-bowel adhesions were equally prevalent in the group with (80%) and without (70%) chronic pain syndrome.

Five patients had dyspareunia only, whereas 25 had pain during daily activities; 15 of these also had dyspareunia (Table I). Of the 25 patients with chronic pain during daily activities, 14 (56%) had either complete resolution of pain (n = 9, 36%) or at least 50% reduction of pain (n = 5, 20%) at follow-up. Seven (28%) had initial improvement, with pain returning to >50% of preoperative levels within 2 to 5 months of the operation (Fig. 1), and four (16%) had no improvement (Table I). The return of pain after transient relief was associated with bowel adhesions at the trend level (p = 0.19). Fourteen of 20 patients (70.0%) with deep dyspareunia had either complete resolution (n = 7, 50.0%) or improved >50% (n = 7, 50.0%) after operative laparoscopy (Table I). In some cases resolution of dyspareunia was apparently hindered by concomitant vaginal factors of tightness and deficient lubrication. In women with both dyspareunia and pain during daily activities, the postoperative courses of both symptoms were similar, i.e., either both improved or both persistent in all cases.

Patients without chronic pain syndrome were significantly more likely to have prolonged relief of pain during daily activities ($p < 0.05$) and relief of dyspareunia ($p < 0.05$) (Table I). When results with daily pain and dyspareunia are combined, these patients were more likely (at the strong trend level, p = 0.06) than women with chronic pain syndrome to obtain good results. Relief of dyspareunia and pain during daily activities was not related to adhesion score in the whole group or in the subgroups with or without chronic pain syndrome.

Comment

Models of pain perception have grown more complicated with time, in part as a response to the need for a better model to explain the complexities of chronic pain syndromes. The ancient Cartesian theory, which postulated the existence of neurons having the single function of carrying pain signals to the brain, has given way to the gate control theory[11] and to cognitive-behavioral models.[13] These models integrate the influences of personality, affect, organic changes, sensory thresholds, and cognitions about pain and its causes in a manner that avoids clear demarcation between psychologic and physical causes for pain but rather recognizes their intricate and interdependent relationships. This study suggests that lysis of pelvic adhesions may indeed be a useful procedure in many circumstances. Pain associated with adhesions is less often relieved when accompanied by a chronic pain syndrome, i.e., diminished physical activity, vegetative signs of depression (usually sleep disturbance), and substantial alteration of the patient's role in the family. The results are most consistent with a model of pain perception that integrates physical and psychologic factors.

Our study replicates our previous finding[7] that the anatomic site of the pathologic condition often matches well with the reported location of pain but that the intensity of pain does not correlate with the amount of disease present. Similar findings have been noted in the case of endometriosis.[14]

In short-term follow-up the majority (88% in this study) will report relief of pain. About one fourth will note return of pain within 3 to 5 months, emphasizing the need for long-term monitoring. Women in this study with chronic pain syndrome, more often than those without, tended (at trend level) to have pain return after transient relief. The clinical dilemma after pain returns becomes whether to pursue further lysis of adhesions or to follow other therapeutic avenues. These results support the approach that any evidence for elements of a chronic pain syndrome should prompt application of nonsurgical therapies, regardless of whether further lysis of adhesions is performed.

Several investigators have pointed out that pelvic abnormalities in general[5, 15] and adhesions in particular[6] may be no more prevalent in women with pain than in those who are pain free. The degree and location of adhesions in these comparative studies are not specified. The comparison populations in this latter study[6] were possibly self-selected as pain free, i.e., sufficiently comfortable to allow pursuit of infertility treatment, and hence were not a valid comparison sample. These studies imply that, like endometriosis, pelvic adhesions apparently do not always cause pain but are a source of nociceptive signals in many cases. This study suggests that adhesions involving large or small bowel may play a more significant role in pelvic pain than adhesions in other areas, especially in terms of the chance of recurrence of pain after laparoscopic lysis of adhesions.

Many studies have evaluated the impact of lysis of adhesions on fertility, but only a few[16-18] have examined the role of this procedure for pain relief. In primary care settings, the proportion of patients helped by lysis of adhesions may be as high as 84%,[17] and, even in the case of severe adhesions with many preceding operations, the majority may be helped.[16]

The precise role of psychosocial factors in chronic pelvic pain is uncertain. In the apparent effort to avoid confounding variables, many studies examining the psychologic profile of the pelvic pain patient have focused on "laparoscopy negative" women or compared the psychologic profiles of women with and without organic findings. Such studies have emphasized the role of psychosocial factors such as a distressed or multiproblem family of origin, sexual abuse, marital discord, and psychiatric diagnoses such as depression, anxiety, and personality disorders.[15, 19] These factors no doubt play substantial roles in many patients. We postulate that a person with such difficulties may be ill equipped to cope with the uncomfortable somatic sensations accompanying any disease process and perhaps especially vulnerable to impairment when the disease involves a body area (the reproductive or sexual system) that may have been the target of abuse. However, the observation that these factors may complicate the presentation of symptoms in the presence of organic disease does not demand the conclusion that the organic disease is of no significance. These data support the notion that lysis of adhesions is useful but should be accompanied by additional psychologic evaluation and treatment in these women displaying vegetative signs of depression or significant alteration of family roles. Further clinical studies are needed to clarify subtypes of patients with chronic pelvic pain, to understand the role for lysis of adhesions in women with significant psychosocial risk factors, and to better understand the types of nonsurgical therapies most likely to be effective.

Discussion

DR. ROBERT B. ALBEE, JR., Atlanta, Georgia (Official Guest). Pelvic pain that has no explanation is one of the most frustrating problems that the gynecologist faces. However, even more exasperating is the failure of pelvic pain to respond to the appropriate and thorough treatment of pelvic pathologic conditions.

Drs. Steege and Stout have presented a prospective comparison of consecutive patients undergoing laparoscopy for pelvic adhesions. Three preoperatively evaluated parameters are then used to isolate a subgroup of patients whose successful resolution of pain is different and less than the remainder.

In the study group all patients had pain for ≥6 months and none had complete relief of pain from previous medical or surgical treatment. The preoperatively evaluated parameters were as follows: (1) the presence of impaired physical function (work, recreation, etc.), (2) the presence of vegetative signs of depression (sleep disturbance aside from being awakened by pain, loss of appetite, psychomotor retardation), and (3) the presence of alteration of family roles.

The findings suggest that in patients with prolonged pain and previous treatment failure, there may still be good reason to try to eradicate residual adhesions; however, if two of the three above-listed conditions are present (i.e., chronic pain syndrome), the chances of long-term relief from pain are less than if those conditions are not present.

This information is going to come as no surprise to clinicians, yet there is almost nothing in the literature that prospectively evaluates these specific variables.

The authors concluded that psychologic treatment should be used in addition to the surgical lysis of adhesions if patients have diminished physical activity and vegetative signs of depression or significantly altered family roles.

I believe it also would be appropriate to counsel these individuals before operation regarding their reduced relative success compared with the group without chronic pain syndrome. This would give each individual the opportunity to reconsider any other factors that may be related to their pain. It also more appropriately defines the chances of long-term success.

Drs. Steege and Stout do not specify the types of psychologic treatment being used or recommended in these patients. Typically behavioral modification, counseling, group therapy, and drug therapy (such as anxiolytics and antidepressants) all have been used. In virtually all of these treatment avenues, definitive treatment depends on the individual's ability to acknowledge and assess all factors contributing to the pain. Thus, as the authors have recommended, we must not pass up this opportunity to encourage each patient to seek further evaluation and treatment of the other factors involved.

I would like to ask the authors if it is safe to assume that they have excluded from this study group all patients who were found to have any concomitant pelvic disease in addition to adhesions? I think it is important to point out that the validity of their conclusioins would certainly be affected by the presence of endometriosis, myomas, ovarian cysts, etc., because the prevalence of other diseases was not indicated in the two study groups.

If other diseases were excluded, I would like to ask to what extent an effort was made to rule out the presence of what is being referred to as microscopic endometriosis?[1, 2]

DR. DOROTHY E. MITCHELL-LEEF, Atlanta, Georgia. You discussed the fact that you have encountered adhesions. What are you using for the prevention of further adhesions, and are you considering repeat laparoscopy in those patients who experience a return of pain?

DR. J. GREG JOHNSON, Greenville, South Carolina. What is the role of uterosacral ablation in the control of pain in a patient with an intact uterus?

DR. WALLACE C. NUNLEY, JR., Charlotte, North Carolina. In the six of 10 patients with chronic pelvic pain syndrome who did not respond over the long term, did you offer referrals or psychologic evaluation, and if so, would you share information as to their subsequent course?

DR. JAROSLAV F. HULKA, Chapel Hill, North Carolina. Dr. Steege is to be congratulated for pointing out the transient nature of some of the cures that we have relied on for the management of pain. His illustration showing a 1-month cure and a six-month recurrence is important in our reevaluating the literature about the efficacy of pain medication and surgery. I want to ask a question about the efficacy of psychiatric therapy. Given that the patients do not respond to surgery, what is your experience about the efficacy of psychotherapy; in other words, how can we help these patients?

DR. STEEGE (Closing). As I mentioned, we did use the Interceed adhesion barrier as a part of our standard procedure. I don't mean to say that I am convinced that it is the be-all and end-all of adhesion prevention. I think that it should be evaluated and used laparoscopically, as opposed to generalizing from its use during laparotomy, because laparotomy in itself predisposes to adhesion recurrence far more than does laparoscopy. In laparoscpic reports available so far, there is a reduction of adhesion formation by 50% to 60%, regardless of what kind of operative technique is used. Whether you use Hyskon or Interceed, the results are similar.

The use of uterosacral ablation applies primarily to dysmenorrhea. I don't think its use applies to chronic pelvic pain. Nineteen of 30 patients in our series had hysterectomy. Of those who had pain, seldom was it totally central pain, and that is because these are patients with adhesions only. Although there were some with adhesions to the fundus of the uterus, most of them had adhesions involving the adnexa and bowel. Seventy-five percent of the total group had adhesions involving the large bowel, small bowel, or both. I believe that uterosacral ablation is useful only for central pelvic pain. The nerve supply of the adnexa and the pelvic sidewalls doesn't go through the uterosacral ligaments.

The follow-up of nonresponders is difficult because they are relatively few and because they are a very heterogeneous group in terms of their social situations and their psychiatric histories. I should mention that one obvious thing missing in this article is any assessment of whether sexual abuse, during either childhood or adult life, had been a part of their history. I think that many of you are aware of recent studies showing that in women experiencing chronic pelvic pain, defined in a very similar way—≥6 months—about 60% had been sexually abused at some point in life. The question then becomes, "Is there a predisposing factor that makes a person vulnerable to whatever nociceptive signals come from whatever pelvic abnormality there is, or is there a current, important active ingredient that needs to be addressed?" I think that question is far from settled. Clinically, when I get that history, I have a hard time knowing quite what to do with it, on the basis of not knowing how it connects to the symptoms and having seen discouraging results in the psychotherapeutic treatment of those who have been victims of sexual abuse. Nonresponder follow-up is a far more difficult question to answer and involves much more complex levels of assessment. I think our results with those have been very mixed. We do use antidepressants, psychotherapy, inpatient psychiatric hospitalization, and a variety of different treatments. Again, it is very difficult to generate homogeneous groups to evaluate results.

There are several articles in the literature that talk about psychotherapy or behavioral therapy for the treatment of chronic pelvic pain. One was done at a military facility in which a chronic pain clinic was the ultimate referral for anyone with chronic pain. They demonstrated that the frequency of hysterectomy could be drastically reduced by such referral. The problem in applying this to general practice is that people in the military system are a captive audience. They do not have the option for private medical care, short of paying for it themselves and going outside the system to have a hysterectomy. I think that in many of our populations if we say, "You don't really need a hysterectomy," many will simply walk out and find someone else who will perform a hysterectomy. Therefore I am not sure the results of the military study apply.

Individual psychotherapy, in the sense of a typical psychodynamically oriented approach, is less likely to be useful. What is more likely to be useful, generalizing from work with chronic pain in other areas such as back pain, headache pain, etc., is a more behavior-oriented program that takes a more rehabilitative approach, maximizing what positive elements in the person's life are left, approaching the roles within the family that may have changed, looking at the role of the husband and the children, etc., in the perpetuation of the chronic pain syndrome. Thus the burden of responsibility is basically taken away from the symptom bearer and the family system is examined. I think that is more likely than individual psychodynamically oriented psychotherapy to be effective.

Combined interferon alfa and doxorubicin in the treatment of advanced cervical cancer

Charles E. Welander, MD, Howard D. Homesley, MD, and Rolland J. Barrett, MD
Winston-Salem, North Carolina

Interferon alfa and doxorubicin have been shown to have synergistic effects when tested in vitro with cells derived from cervical cancers. A clinical trial was designed, testing interferon alfa plus doxorubicin in patients with advanced or recurrent cervical cancers. Twenty-one patients were given interferon alfa, 10 million units per square meter intramuscularly and 10 million units per square meter intravenously over a 30-minute infusion period. One hour later 20 mg/m^2 doxorubicin was given intravenously slowly over a 2-hour period. Treatments were repeated once weekly for 3 weeks. Initial response evaluation was done at week 5, and treatment was continued on an every-other-week schedule for patients showing favorable responses or stable disease. Bone marrow, hepatic, and renal toxicities were minimal. Fever and malaise were the major sources of toxicity. Of the 17 evaluable patients, six had clinical partial responses. Two of the responders have enjoyed more than 5 years' survival. This regimen is well tolerated and does have efficacy in some patients with advanced cervical cancers. (AM J OBSTET GYNECOL 1991;165:284-91.)

Key words: Cervical cancer, chemotherapy, interferon, interferon and doxorubicin

Advanced malignancies after failure of primary therapy are generally re-treated with only palliative goals in mind. Cancers arising in the uterine cervix that are first seen as advanced or metastatic disease are commonly treated with primary radiation therapy. Cure rates achievable with radiation therapy are reportedly as high as 65% for stage IIB disease and up to 35% for stage IIIB disease.[1] However, even under the best of circumstances, there will be many patients with persistent disease after therapy, either because of failure of radiation to sterilize bulky pelvic disease or from metastatic tumor appearing in distant sites.

Chemotherapy for primary malignancies of the cervix has had very limited success in the past. Reasons for chemotherapy failure include probable inherent resistance of tumor cells to many chemotherapeutic agents in addition to the difficulty in delivering therapeutic concentrations of drugs to an irradiated tumor bed. These realities notwithstanding, attempts continue to identify helpful treatment for patients who experience recurrent cervical cancer.

Preclinical data have demonstrated that tumor cells from patients with cervical cancers do show a limited degree of sensitivity to the antiproliferative effects of interferon alfa.[2] Further enhancement of in vitro antiproliferative effects has been shown when interferon alfa is combined with doxorubicin.[3, 4]

This report is of a phase II clinical trial that was based on the preclinical clues that combined interferon alfa and doxorubicin have antiproliferative activity in the treatment of primary cancers of the cervix. The study design, including the novel doses and schedules of drugs administered, was based on in vitro data.[5]

Material and methods

Twenty-one patients with primary cancer of the uterine cervix were treated at Bowman Gray School of Medicine of Wake Forest University, according to this protocol, using combined interferon alfa and doxorubicin. Each patient signed an informed consent approved by the Bowman Gray Clinical Research Practices Committee. Entry criteria included histologic confirmation of advanced or recurrent cervical cancer. All patients were required to have either measurable or evaluable tumor that could be assessed for response. Performance status for each patient was 0, 1, or 2 (Eastern Cooperative Oncology Group criteria[6]). Patients must have recovered from any toxicity resulting from prior radiation therapy or chemotherapy. Of these 21 patients, 14 had squamous cell type, five had adenosquamous tumor, and two had primary adenocarcinoma of the cervix. There were no patients entered with the small cell variant of cervical cancer.

The treatment schema was based on clues derived from in vitro testing of tumor cells exposed to sequen-

tial interferon alfa and doxorubicin.[7] The purpose of the study design was to give both drugs in close sequence. Patients received treatment only when both agents could be given safely. The schedule of drug administration is summarized in Fig. 1. Interferon alfa was administered partly as an intravenous infusion of 10 million units per square meter over a 30-minute period to achieve rapid peak blood levels. An additional intramuscular injection of 10 million units per square meter also was given at the same time and served to extend the serum levels of interferon alfa for a period >8 hours. After a 30-minute waiting time, the 2-hour doxorubicin infusion was begun. The 20 mg/m² dose of doxorubicin selected was as high as was believed to be manageable on a weekly basis. The infusion was extended over a 2-hour period to prolong the levels of doxorubicin beyond those seen when rapid intravenous bolus infusion is given. Acetaminophen was given according to the schedule shown in Fig. 1. The initial treatment, referred to as the induction phase, included three weekly treatments of interferon alfa followed by doxorubicin. A 2-week rest followed, after which evaluation of initial response was made. Patients who showed any favorable response or even stable disease were continued on maintenance therapy, consisting of the same dose schedule given every second week. Patients had treatment discontinued when the disease progressed, when toxicity was noted, or when they desired to stop therapy.

Interferon alfa used in this study was provided by the Schering Corporation, Kenilworth, N.J. This interferon (Intron A) is of recombinant type and highly purified.

Background information for each new patient is noted in Table I.

For a patient to be considered evaluable in this study, she had to complete the three induction courses of treatment and have the measurable/evaluable indicator lesion reassessed for response. Response evaluation was determined by conventional definition. A complete response was determined clinically, requiring that all of the indicator lesion disappear, determined by two observations not <4 weeks apart. Partial responses were defined as >50% shrinkage of the indicator lesion, lasting at least 4 weeks. Toxicity was graded according to World Health Organization criteria,[8] particularly noting hematologic, hepatic, and renal toxicity, as well as febrile morbidity and consitutional side effects.

Results

Of the 21 patients entered onto this study, 17 were evaluable for responses. Reasons for each of the four patients declared unevaluable are summarized in Table II. Clinically determined responses to therapy were ob-

21	2/81	11/84	Vaginal mass 6 × 5 cm	1	Refused therapy	Died 11/85

served in six of the 17 evaluable patients. Each experienced a partial response, noted at the completion of therapy. There are two patients of particular interest who have experienced long-term remissions. Patient 1 (see Table I) had persistent pelvic disease after primary radiation therapy for a stage IIIB lesion. She received three induction courses in February 1984, followed by three additional courses of maintenance therapy. Treatment had to be discontinued in early Mary 1984 when she had a hip fracture. On clinical evaluation she had no apparent tumor remaining but did have induration in the pelvis after radiation therapy. It was not possible on clinical examination to be sure that she was totally free of tumor. Hence she has been considered to be a partial responder. However, she remains free of any recurrence or symptoms of new disease as of October 1990. She has had no additional therapy since May 1984.

Patient 2 had stage IIB cancer discovered at the time of surgery for uterine fibroid tumors. The carcinoma was surgically cut across at the parametrial edges of the specimen and was subsequently treated with postoperative pelvic radiation therapy. The vaginal apex failed to heal after surgery and radiation, partly related to persistent parametrial tumor and the radiation effect on the tissues. She was given five courses of intravenous cisplatin chemotherapy, without any apparent antitumor response. At the time of entry into this study in November 1984, she had an 8 × 8 cm mass at the vaginal apex. After completing the 3-week induction therapy, she already had a partial response noted. She had an additional four courses of maintenance therapy. Treatment was stopped at this point when surgery was required because of a colon obstruction. An ileostomy was done by her surgeon, bypassing the entire colon. Neither resection of the colon nor dissection of the pelvis was attempted. The operative note described the peritoneal cavity as being free of any gross tumor. Approximately a year later she did have a new site of squamous cancer along the left labium minus. This appeared as a 1 cm ulcerative lesion, which was treated with an iridium 192 implant in December 1985. This lesion healed without evidence of persistent carcinoma. Whether this vulvar lesion was a recurrence of the earlier cervical primary or a new lesion was not clear. Although further follow-up failed to reveal any persistent disease, she also has been continued in the records as showing a partial response in this study. At the time of her last follow-up in July 1989, she had not received any further therapy and remained clinically free of apparent disease.

Patients 3, 4, and 5 (see Table I) experienced partial responses and also had no further treatment after completing this protocol therapy. Each patient has subse-

quently died, with survival durations of 9, 10, and 6 months, respectively. Patient 6 was on study from May to November 1985, initially experiencing a partial response of a measurable lung mass. Tumor progression was first seen in November 1985, at which time she had new chemotherapy started. The progression-free interval related to this study was 6 months.

The remaining patients had stabilization of disease for a period of time, followed by ultimate disease progression and death.

Bone marrow toxicity from this regimen was minimal (Tables IIIA and IIIB). Only one patient (No. 4) experienced granulocytopenia to levels <1000/mm^3. Thrombocytopenia was not seen in any patient from this group. There were no measured toxic effects on renal or hepatic function. One patient (No. 6) did experience grade III febrile morbidity. This was transient and resolved without sequelae. Another patient (No. 16) had grade III nausea and vomiting, which was also temporary.

Comment

Evaluation of this phase II study with a novel drug combination such as interferon alfa and doxorubicin raises at least three questions: (1) Is there clinical activity when a biologic response modifier is used together with a cytotoxic drug in the treatment of cervical cancer? (2) Are there patient factors that are associated with increased probability of good response? (3) Can preclinical studies be used to design clinical trials, not only in selection of drugs but also as a guide to optimal sequencing and dosing?

The first question regarding clinical activity is easy to answer in a superficial way. There does appear to be some effectiveness of combined interferon alfa and doxorubicin in six of the 17 evaluable patients who had advanced cervical cancers. Of particular note is the long duration of response seen in two of the patients, each of whom had failure of previous standard therapy. A more fundamental question is whether both drugs are necessary to achieve clinical responses. Data from the 1970s have been reported on patients with advanced cervical cancer who were treated with doxorubicin alone or in combination with other standard cytotoxic drugs.[9, 10] Clinical responses have been seen in <20% of patients, with median survival duration <4 months. The authors of these articles concluded that doxorubicin alone had little activity in the treatment of advanced squamous cell cancer of the cervix. There is one report from Yugoslavia in which topical and intralesional interferon alfa treatment for cancer of the cervix was used.[11] The drug preparation used in this particular report was not purified recombinant interferon alfa but a natural preparation. Some antitumor activity was reported in six of 15 patients, although clinical evaluation parameters were not always clear. There is no similar study of single-agent interferon alfa reported from any institution within the United States. We are left with the question whether the clinical responses seen have resulted from interferon alfa activity alone or whether there truly is some synergistic activity of interferon alfa plus doxorubicin (as in vitro studies suggest). A single-arm phase II trial such as this one will not be able to answer that question.

Historic experience with cytotoxic drugs and biologic response modifiers would suggest that there are patient factors that can be predictors of good responses. Good performance status, younger age, longer progression-free interval before relapse, complete responses from initial therapy, and smaller tumor burden all seem to be favorable prognostic features. In looking at these questions, we have divided our 17 evaluable patients into the six responders and the 11 nonresponders and looked at several of the parameters individually, with this treatment regimen (Table IV). Histologic cell type may be of significance. Each of the six responding patients had squamous tumor. None of the patients with adenocarcinoma or adenosquamous tumor showed measurable responses. Other host factors such as age, performance status, and duration of disease before entry into this study do not seem to be different between responders and nonresponders. All of the patients had tumor volume >1 cm.

Table IV. Patient factors correlated with treatment responses

Factor	*Average for responders*	*Average for nonresponders*	*Average for total group*
Age (yr)	52.5	46.5	48.6
Performance status	1	1.1	1.05
Duration of disease before entry in study (mo)	10.3	16.9	14.6

The question of drug delivery to tumor cells within a previously irradiated field is important to note. Interestingly, four of the six with response had evaluable disease within a previously irradiated field. Patients having only lung metastases (which was always outside the radiated field) showed responses in only one of four cases.

The last question concerns the application of preclinical studies as a guide in the design of clinical trials. Previous work has shown that certain in vitro tests such as a human tumor colony–forming assay can be used to predict antitumor activity of certain drugs.[12] Clinical correlations have been high when single drugs have been tested in vitro and compared with single-agent therapy in patients. However, no prospective trials have been done correlating in vitro human tumor colony–forming assay results with clinical use of doxorubicin or interferon alfa in the treatment of cervical cancers. We only know that cell lines that have been derived from human cervical cancers have shown additive and occasionally synergistic antiproliferative responses when treated with combined interferon alfa and doxorubicin.[3, 5]

Conclusions to be drawn include the observation that six of 17 evaluable patients with advanced or metastatic cancer of the cervix treated with sequential interferon alfa and doxorubicin have shown measurable clinical responses. Toxicity has been minimal, even in patients who have had pelvic radiation therapy. There does not appear to be a selection bias of only favorable patients being entered into this study. Looking to the future, preclinical data do seem to be useful in the design of phase II trials, particularly when there are only limited clinical parameters available on which to base new study designs.

Discussion

DR. JAMES P. LAPOLLA, Tampa, Florida (Official Guest). The incidence of invasive cervical cancer, although declining, still accounts for 12,000 to 13,000 cases in the United States annually, with an expected 6000 to 7000 deaths. Currently, chemotherapy for recurrent disease is a less than satisfactory treatment modality, and newer agents or treatments with greater antineoplastic activity are needed. As we are aware, the most active single agent for the treatment of advanced or recurrent cervical cancer is cisplatin. The overall response rate to cisplatin averages about 25% for squamous cervical cancer, and the median survival of those responding is 9 months, on the basis of Gynecologic Oncology Group data.[1] Cisplatin-based combination therapy has not been demonstrated to improve survival over single-agent cisplatin to date.[2] Doxorubicin as a single agent for the treatment of advanced cervical squamous carcinoma has an overall response rate of 16% on the basis of a number of studies and would be classified as a drug with moderate to low activity for squamous cervical cancer.[1] Clinical trials using interferon for the management of advanced cervical squamous carcinoma are scarce. In 1981 Ikic et al.[3] using unpurified human interferon topically or topically and intramuscularly as a single agent reported that six of 15 patients with primary cervical squamous carcinoma manifested a response to treatment. In those responding to treatment five had no residual tumor and one had only residual microinvasion on the surgically resected specimens. Recently Kavanagh et al.[4] reported on the treatment of 25 patients with recurrent cervical squamous cancer treated with the combination of interferon alfa, 5-fluorouracil and cisplatin. They noted an overall response rate of 36% (9/25), similar to the rate in the current study, with two thirds of responding patients having a complete response. Survival data, however, were not reported. Welander et al. have presented to us a unique clinical trial in which patients with advanced or recurrent cervical carcinoma are treated on the basis of promising preclinical data suggesting that sequential treatment of cervical carcinoma cell lines with recombinant interferon alfa, then doxorubicin resulted in either synergistic or additive cell growth inhibition, compared with interferon alone, as demonstrated by in vitro chemotherapy testing with the human tumor clonogenic assay. Both the dose and scheduling of these drugs were based on in vitro data that suggested that interferon-induced cytotoxicity was related to maximum concentration achieved and to a prolonged exposure time. Doxorubicin treatment before interferon treatment did not result in a synergistic interaction, but after interferon exposure it did.[5]

Dr. Welander has previously reported to this association his work regarding the human tumor clonogenic assay for chemotherapy testing.[5] It was reported that for single-agent chemotherapy prospectively selected on the basis of the human tumor clonogenic assay, the "sensitive" predictive accuracy was 90% and the "resistant" predictive accuracy was 100%, indicating that the assay's prediction of response, or lack of response, to single-agent therapy was excellent. Other investigators who have correlated in vitro prediction with clinical response have found a "sensitive" predictive accuracy of 60% to 70% and a "resistant" predictive accuracy of 90%.[7] In this study 35% of cervical cancers were responsive to the interferon and doxorubicin combination chosen on the basis of human tumor clonogenic assay sensitivity testing. Although the predictive accuracy is less than expected for single agents considering the heterogeneity of cervical cancer cells, I think the results are quite remarkable. This response rate certainly is comparable to response rates observed with Cisplatin alone. It is also remarkable that two of six patients who did respond had prior cisplatin therapy. These results are promising, and larger phase II trials are certainly in order so as to gain more accurate information regarding the sensitivity of cervical squamous carcinoma to this combination-drug regimen.

Dr. Welander, you suggest that patient factors such as age, performance status, and disease duration before interferon-doxorubicin therapy did not differ for responders and nonresponders, so that patients clinically seemed comparable. However, for each patient treated in this study, were samples of each individual patient's tumor analyzed by the human tumor clonogenic assay for chemosensitivity to sequential interferon-doxorubicin therapy, and if so how did these results correlate with patient response?

Second, you have indicated in a previous report that the combination of interferon with cisplatin demonstrated additive effects on the human tumor clonogenic assay.[5] Have you done any trials using the three drugs—interferon, doxorubicin, and cisplatin—together, and if so are the results any better than with the two-drug interferon-doxorubicin protocol?

Finally, you previously indicated in 1983 that more experience would be necessary before you could recommend the human tumor clonogenic assay as a decision-making tool. In 1991 should clinicians use this assay for selecting chemotherapy for a patient with recurrent cervical malignancy?

DR. EDWARD J. DENNIS, Columbia, South Carolina. About 8 years ago, in Columbia, South Carolina, in a 1-year period we had 50 cases of carcinoma of the cervix that were stage IIB or above. The average age of the patients was ≥55 years. We see advanced disease in patients with no previous therapy. Do you see any advantage, recognizing that there may already be positive periaortic nodes outside the field of radiation therapy, to using your chemotherapy regimen as initial therapy before or in combination with radiation treatment?

DR. WELANDER (Closing). We have done human tumor clonogenic assay sensitivity testing on a random basis but not as a formal part of this particular protocol. If we were in an ideal world, it would be our goal to do that. We would design a study that would prescreen patients by looking at their tumor drug-sensitivity pattern in advance. It would be easiest in patients who have not had radiation therapy. Laboratory findings suggest that it would be a good idea to combine interferon with one or more drugs, such as doxorubicin or cisplatin.

In Atlanta, for the bulky stage IB tumors that are >3 cm in diameter, we administer three weekly cycles of chemotherapy and then perform surgery. Although we have not done it, I believe this regimen could be used in advanced IIB or IIIB disease. Chemotherapy would then be followed by radiation therapy. It is a short course that does not significantly delay standard therapy and may help with outcome.

Primary invasive vaginal carcinoma

Gary L. Eddy, MD, Richard D. Marks, Jr., MD, M. Clinton Miller III, PhD, and Paul B. Underwood, Jr., MD

Charleston, South Carolina

A review of primary vaginal carcinoma treated at the Medical University of South Carolina from January 1970 through December 1989 included 76 squamous carcinomas, 12 adenocarcinomas, and 3 undifferentiated carcinomas. Staging was done according to the system of the International Federation of Gynecology and Obstetrics as modified by Perez et al. Stages I, II, III, and IV included 25, 39, 15, and 12 patients, respectively. Corrected 5-year survival rates were 73% for stage I, 39% for stage II, 38% for stage III, and 25% for stage IV. Sixteen percent of patients had received prior pelvic radiation. Invasive cervical cancer preceded vaginal cancer in 21% of patients. Detection of cancer was accomplished by routine cytologic testing in 17% of patients, palpation of an asymptomatic mass in 10% of patients, or palpation of a symptomatic mass in 72% of patients. Eighty-seven percent of patients were treated with radiation therapy. Survival curves of patients grouped by stage and other potential prognostic factors were compared. Lower stage ($p < 0.01$), younger age ($p < 0.02$), and no symptoms at detection ($p < 0.01$) were statistically significant favorable prognostic factors. Histologic type, extent of vaginal involvement, vaginal location, prior radiation therapy, prior cervical cancer, and prior hysterectomy are factors that did not significantly affect survival. (Am J Obstet Gynecol 1991;165:292-3.)

Key words: Vaginal cancer, prognostic factors, radiation therapy

Primary invasive carcinoma of the vagina accounts for 1% to 2% of all gynecologic malignancies.[1-5] As a result experience with this disease at any given institution is usually limited. Controversy remains concerning factors that significantly affect survival, appropriate staging of the disease, and ideal therapy.[5-8]

A report from the Medical University of South Carolina analyzed 31 cases of invasive carcinoma evaluated and treated from 1954 through December 1969. This report reviews the experience with 91 subsequent cases. Specific attention is placed on analysis of factors affecting survival.

Material and methods

The Tumor Registry at the Medical University of South Carolina was used to identify potential cases of primary vaginal carcinoma that were evaluated and treated at the Medical University of South Carolina from January 1970 through December 1989. Patients whose vaginal tumors also involved the vulva or cervix, who had carcinoma of the cervix or vulva within the preceding 5 years, or who had a history of endometrial carcinoma were excluded. The International Federation of Gynecology and Obstetrics (FIGO) staging system as modified by Perez et al.[9] was used prospectively. For all accepted cases it was possible to determine extent of disease from clinical records. Appropriate assignment of FIGO stage for each case was confirmed.

Available records included Tumor Registry patient abstracts, hospital charts, outpatient records, operative notes, and pathology reports. Patient follow-up was documented by the Tumor Registry and included records at the Medical University of South Carolina, as well as direct communication with patients and referring physicians.

Patient survival was plotted with the life-table method of Kaplan and Meier.[10] Potential risk factors influencing survival times of patients were examined by means of the Cox proportional hazards model.[11] Stepwise regression with the maximum partial likelihood ratio method was used to select the most significant factors. Survival curves were compared with the use of the log rank test.[12]

Results

Table I lists the number of patients with different gynecologic malignancies treated at the Medical University of South Carolina from January 1970 through December 1989. Ninety-one patients with primary vaginal carcinoma were treated. Seventy-six patients (84%) had epidermoid carcinoma, 12 patients (13%) had adenocarcinoma, and 3 patients (3%) had undifferentiated carcinoma. Table II lists these patients by FIGO stage modified as proposed by Perez et al.[9] Fifty patients

were white and 41 were black. This is in agreement with the ethnic composition of our hospital population. The median age of patients was 60 years with a range of 21 to 88 years. Sixty-eight (75%) patients were at least 50 years old. Parity was known for 75 of our 91 patients. Seventeen patients (23%) were nulliparous and 26 (35%) were para ≥5.

Significant gynecologic events in the medical history are listed in Table III. For those patients who had a history of cervical cancer, the median interval between diagnosis of the cervical carcinoma and diagnosis of vaginal carcinoma was 168 months with a range of 68 to 338 months.

A means of detection could be identified in 87 of our 91 patients. Diagnosis was made by biopsy in all cases. This biopsy was prompted by a symptomatic mass in 63 patients, vaginal cytologic abnormalities in 15 patients, and an asymptomatic mass noted by an examiner in an additional 9 patients. For 85 patients it was possible to determine whether they had specific symptoms. This information is shown in Table IV. For 54 of 63 patients with symptoms it was possible to determine the duration of symptoms. The median duration of symptoms was 3 months. Thirty percent of patients had symptoms for ≤1 month, and only 22% of patients had symptoms for >6 months. A precise anatomic location of the tumor could be specified for 84 patients. The cancer was confined to the upper one third of the vagina in 33 patients, the middle one third in 5 patients, and the lower one third in 8 patients. The disease occupied the upper two thirds of the vagina in 16 patients, the lower two thirds of the vagina in 4 patients, and the entire vagina in 18 patients. In 11 of the 29 patients with prior hysterectomy, the disease was confined to the vaginal apex. The disease was located principally on the anterior vaginal wall in 14 patients and on the posterior vaginal wall in 10 patients. The right vaginal wall was the principal site in 15 patients, and the left vaginal wall was the principal site in an additional 18 patients.

The initial treatment of these 91 patients is detailed in Table V. The radiation therapy technique is described in Table VI. The sum of the teletherapy midplane tumor dose, brachytherapy vaginal rad surface dose, and interstitial radium mid tumor dose could be calculated for 76 of the 79 patients receiving radiation therapy. The median value was 80 Gy with a range from 16 to 121.7 Gy. Radiation therapy complications necessitating hospitalization occurred in 7 patients (9%). Transient proctitis occurred in 2 patients. An additional 2 patients had vulvar excoriation that required topical care and necessitated temporary interruption of therapy. One patient had a vulvar ulcer that required approximately 4 months to heal. One patient required a 4-day hospitalization and intravenous hydration for acute enteritis. A vesicovaginal fistula developed in a patient with bulky pelvic disease while she was receiving teletherapy.

IVB	6	7
TOTAL	91	

Exenterative procedures were used in 8 patients. Anterior exenteration was performed in 3 and 5 underwent total exenteration. Exenterative procedures were performed because of persistent disease after radiation therapy in 6 of 8 cases. There were no operative deaths. Only 3 patients died of persistent or recurrent vaginal cancer. Four patients have survived free of disease from 80 to 134 months. A rectovaginal fistula developed in one patient after anterior pelvic exenteration and postoperative intracavitary and external radiation therapy for stage IVA disease. She survived 253 months before dying of an unrelated cause.

Eleven patients received chemotherapy, ten of them because of a recurrence. Seven of these 11 patients received cyclophosphamide (Cytoxan) alone. One patient received melphalan (Alkeran). The remaining 3 patients received combinations containing doxorubicin (Adriamycin) and Cytoxan. No objective responses were noted.

A survival curve for all patients grouped by stage is shown in Fig. 1. Potential risk factors influencing survival times of patients were examined by means of the Cox proportional hazards model.[11] Stepwise regression with the maximum partial likelihood ratio method was used to select the most significant factors. Lower stage ($p < 0.01$), younger age ($p < 0.02$), and lack of symptoms at detection ($p < 0.01$) were identified as significant favorable prognostic factors. Anatomic location,

extent of vaginal involvement, prior pelvic radiation therapy, prior cervical cancer, and prior hysterectomy were not identified as significant risk factors. Survival curves for patients with adenocarcinoma compared with those for patients with epidermoid carcinoma by log rank test showed no significant difference in survival curves ($p = 0.29$).[12] Comparison of survival curves in the 39 patients with FIGO stage II disease divided into groups IIA and IIB as suggested by Perez et al.[9] did not show a statistically significant difference ($p = 0.23$).

All 6 patients with stage IVB died of disease from 1 to 45 months after diagnosis. Three of 6 patients with stage IVA disease survived >5 years without recurrence. All 3 survivors underwent pelvic exenteration and received radiation therapy.

Comment

The treatment schema for vaginal cancer exhibited in this study is similar to that in many reports.[1, 2, 6, 8] Surgery alone was used in only 9% of patients and was principally confined to those with stage I or stage IIA disease. Radical surgery was not routinely performed for such patients as described in other reports.[7, 13] According to the recommendations of Rutledge,[1] Prempree et al.[14] and Perez and Camel,[8] even early lesions were treated principally with radiation therapy. Forty percent of our patients with stage I were treated with radiation therapy alone and an additional 40% were treated with a combination of radiation therapy and partial vaginectomy. Two thirds of our patients with stage II were treated with radiation therapy alone with an additional 20% treated with a combination of radiation therapy and surgery.

In spite of the recommendation by several authors that stage I and II lesions with a depth of >½ cm be treated with interstitial radiotherapy,[8, 14, 15] our report and others show that this modality has been infrequently used.[5, 6] Only 4 patients received interstitial radiation therapy in this series. Puthawala et al.[16] are leading proponents for the use of the Syed template for delivering interstitial radiation therapy to such patients. They reported recently on 16 patients with stage II treated with interstitial therapy by the Syed template. Local control was achieved in 14 patients. Twelve of 16 patients were free of disease with a medium follow-up of 50 months. This is considerably better than the 39% 5-year survival noted in our 39 patients with stage II. The potential advantage of interstitial radiation therapy for such patients is not unexpected. The relative intensity of radiation at two different points from a source of radiation is inversely proportional to the square of the distance of each point from the radiation source. With the placement of multiple interstitial radioactive sources, all areas of a large tumor can be close to the radiation source. With intracavitary radiation the vaginal surface is very close to the radiation source while areas of vaginal tumor may be significantly farther away. Thus extremely high vaginal surface doses would be required to produce modest doses deep within the vaginal tumor. Hintz et al.[17] have shown that the tolerance of the vagina is exceeded above 98 Gy in the lower vagina and 140 Gy in the upper vagina. With such relatively low tolerance by the vagina, it is not possible to deliver significant doses from an intravaginal source to vaginal tumors extending more than 1 to 2 cm from the vaginal surface. Nonetheless, much greater clinical experience will be needed to definitively establish the superiority of interstitial radiation therapy in the treatment of vaginal cancer.

Pelvic exenteration was used in 8 patients in our series. Seven patients received radiation therapy and underwent pelvic exenteration. This combined approach resulted in 5-year disease-free survival in 3 of 6 patients with stage IVA. Two other patients with stage IVA were treated with palliative radiation therapy and survived only 7 and 10 months. The remaining patient with stage IVA received palliative radiation therapy and underwent a diverting ileal urinary conduit but was lost to follow-up after 3 months. These results encourage an aggressive approach to stage IVA vaginal carcinoma and support the recommendation of initial radiation therapy followed by an appropriate exenterative procedure.

Our overall 5-year survival for patients with stage IV disease was only 25% because there were no survivors among the 6 patients with stage IVB disease. Dismal results were encountered in this group in spite of the fact that 3 of 6 patients had stage IVB disease on the basis of inguinal metastases with no other evidence of disease beyond the pelvis.

In this series no objective responses were noted in

11 patients receiving alkylating agent chemotherapy. However, all but one of these patients received radiation therapy to the area of recurrence before receiving chemotherapy. It is of interest that a phase II trial of cisplatin in advanced or recurrent cancer of the vagina reported only one objective response in 16 patients with squamous cell carcinoma.[18] This response occurred in 1 of only 2 patients who had received no prior radiotherapy. A similar objective complete response with cisplatin was noted in a patient reported on by Holleboom et al.[19] with a metastatic site outside the radiation treatment port. Another case report by Katib et al.[20] describes a complete response achieved with bleomycin, methotrexate, and cisplatin in a patient with an 8 cm

vaginal mass and a 4 × 2 cm right inguinal metastasis. The patient subsequently received treatment with external and intracavitary radiation and at the time of the report had remained disease free for 7 months. From these reports there is a clear suggestion that chemotherapy is ineffective at sites previously treated with radiation therapy. This supports the use of cisplatin-containing chemotherapeutic regimens administered either concurrently or before radiation therapy. The use of radiation-sensitizing agents with cisplatin may offer the most promise for improved local and distant control of this disease. Given the rarity of this condition cooperative efforts testing this hypothesis would be most helpful.

Discussion

DR. ROLLAND J. BARRETT II, Winston-Salem, North Carolina (Official Guest). Vaginal carcinoma continues to be one of the most difficult gynecologic malignancies to study, as well as to treat. Reports are limited by the relatively small number of patients treated at any one institution. Although the biologic behavior appears to be similar to that of carcinoma of the cervix, cure rates are generally lower in vaginal carcinoma. The most recent FIGO data show an overall cure rate of 54% for carcinoma of the cervix compared with only 39% for vaginal carcinoma.[1] Differences may be due to anatomic features that promote earlier distant spread in vaginal carcinoma, as well as to anatomic limitations to curative treatment. In spite of these difficulties cure rates have improved, primarily because of advances in radiotherapeutic techniques. The disease was essentially considered incurable in the mid 1930s. Survival has steadily improved since that time with this study noting a 46% overall survival. This report of 91 patients treated at the Medical University of South Carolina makes a significant contribution to the literature concerning primarily invasive vaginal carcinoma.

Common patient complaints at the time of initial presentation include pain, bleeding, and urinary difficulties. This study notes that 74% of patients first presented with a symptomatic pelvic mass. Of importance to all gynecologists is the fact that a significant number of cases of vaginal carcinoma are first detected when there are no symptoms but Papanicolaou smear is abnormal. Seventeen percent of cases in this study were detected by Papanicolaou smear alone, a finding similar to those of previous reports. The manuscript did not detail the cytologic diagnosis, but surprisingly 30 of 32 abnormal Papanicolaou smears in the study of Spirtos et al.[2] were interpreted as squamous dysplasia. This information on Papanicolaou smear diagnosis must be viewed in light of the occurrence of carcinoma of the vagina in patients with previous hysterectomy. In the report of Gallup et al.[3] of 28 patients and review of the literature, >40% of patients with carcinoma of the vagina had undergone hysterectomy primarily for benign indications. This study also reports a similar experience. Although previous hysterectomy appears to be a risk factor for vaginal carcinoma, in a recent case-control study reported by Herman et al.[4] matching patients for age and prior cervical disease, no increased risk was found in women undergoing hysterectomy because of benign disease. Using regression analysis Eddy et al. identified detection before symptoms as a favorable prognostic factor. I would first like to ask Dr. Eddy what his recommendations are for Papanicolaou smear screening for vaginal carcinoma in patients with previous hysterectomy in light of the findings reported.

Control of disease in the pelvis continues to be a problem in the treatment of vaginal carcinoma. Preventing local recurrence appears to be dependent on a combination of external therapy and brachytherapy in most patients with stage I or II disease. A midtumor or medial parametrial dose of 70 to 75 Gy may be necessary to achieve tumor control. Because of alterations in vaginal anatomy as a result of age, previous surgery, tumor mass, and previous irradiation, the placement of a vaginal cylinder for brachytherapy is often difficult. In many cases interstitial therapy allows adequate brachytherapy doses to be delivered. The improved overall local recurrence rate of 9% in the report by Spirtos et al.[2] compared with a 41% incidence reported by Peters et al.[5] must be due in part to the increased utilization of interstitial implants. These results appear to be contrary to Dr. Eddy's stated conclusions concerning interstitial radiation therapy. Second, I would like to ask if there is information from this series correlating radiation dose with local control.

Although there is no consensus as to the proper management of primary vaginal carcinoma, radiation therapy is considered the treatment of choice with surgery relegated to a limited role. In reporting the University of Pennsylvania experience with 75 cases of primary squamous cell carcinoma of the vagina, Rubin et al.[6] described 15 patients undergoing radical pelvic surgery with intent to cure. Of particular note is the fact that only 1 of 7 patients undergoing some type of exenterative procedure was alive after 5 years of follow-up. This study is more encouraging concerning the role of pelvic exenteration, with a significantly higher survival rate in patients with stage IV compared with results of most other studies. My third point is to ask Dr. Eddy to elaborate on his recommendation of initial radiation therapy before the appropriate exenterative procedure in patients with stage IVA. In a related question, how were patients with early-stage disease and prior radiation therapy for cervical cancer treated?

Improving survival in patients with vaginal carcinoma will also depend on controlling metastatic disease and extrapelvic failure. This series confirms the present lack of effective chemotherapeutic agents for metastatic squamous cell carcinomas of the lower genital tract. Concomitant radiation therapy and chemotherapy with cisplatin regimens holds promise for improving local control.[7] A reduction in the incidence of extrapelvic recurrence is less certain. Although large cooperative efforts involving many institutions are needed to study this relatively rare malignancy, it is discouraging to note that the Gynecologic Oncology Group has recently been forced to terminate studies of vaginal carcinoma because of difficulties in patient accrual and timely completion of proposed studies.

In spite of these limitations continued study is necessary. This report from the Medical University of South Carolina is one of the largest series reported to date and a welcome addition to the literature. I congratulate Dr. Eddy and his colleagues for this important contribution.

Dr. Eddy (Closing). I believe that all women should have annual Papanicolaou smears, particularly those who have had a hysterectomy. That is because of the ease of performance, the low cost of the test, and the fact that patients who had a hysterectomy made up 32% of our patients with vaginal cancer. Patients who had malignancy detected by Papanicolaou smears were more likely to have microinvasive or stage I vaginal cancer, and they clearly had a better outcome than the other patients. I have spent a lot of time trying to determine how radiation dose correlated with local cancer control. Another study is under way in an attempt to look at this question in depth. All studies are flawed by relatively small numbers of patients. When you break them into subgroups, you get such small numbers of patients that most statistical tests are invalid. We have found that patients who had <55 Gy did so poorly that they significantly affected the survival rate of any group in which they were included. One reason that some patients received <55 Gy is that they died during therapy or they could not have intracavitary radium for any one of a variety of reasons. Therefore looking at absolute numbers creates difficulties. The other problem is in the number that we all quote as "midtumor dosage" or "total midtumor dosage." Both are numbers that have been invented. It is not fair to add external radiation midtumor doses to radiation surface doses and look at the total dosage. Clearly, if the total dosage were delivered by external beam, it would be significantly more powerful and probably would kill all of our patients. There is a great deal of difficulty in looking at raw numbers.

I have been asked to elaborate on our recommendation for radiation therapy before exenterative procedures in patients with Stage IV. It was remarkable that three patients with stage IVA who were treated with radiation were noted to have persistent disease at exenteration and all were cured. I think that this is probably due to good fortune. It was noteworthy that every patient treated for palliation didn't get very much and lived a relatively short period of time. This makes us more interested in being aggressive in considering exenteration in these patients. Another interesting subgroup are those with stage IVB, all of whom died in relatively short periods of time. They also received external therapy, as it was most difficult to give intracavitary therapy for "palliation." Three of these patients were classified as having stage IV disease, only on the basis of positive inguinal nodes. I am tempted to recommend groin dissection and radiation therapy for such patients with consideration for exenteration in patients with persistent central disease. I know that this recommendation is controversial and not based on fact.

How are patients with early-stage disease and prior radiation therapy treated? We were fortunate in that most of our early-stage disease was stage I; some of these patients had microinvasive cancer that was diagnosed after colpectomy. Four of eight such patients were treated by colpectomy alone. Two patients were treated by external radiation therapy, one by external beam therapy and colpectomy, and one by intracavitary radium and external beam therapy. Those eight patients had local control of disease as a result of the therapy.

Analysis of 500 obstetric and gynecologic malpractice claims: Causes and prevention

Charles J. Ward, MD
Atlanta, Georgia

Five hundred obstetric and gynecologic malpractice litigation claims were analyzed to determine the incidence of claims that could not be defended because of breach of standards of care, problems with documentation, or both. Of the 500 claims, 294 were obstetric and 206 were gynecologic. Of the obstetric claims, 79 (27%) were indefensible because of breaches of standards of care (71%), problems with documentation (5%), or both (24%). Of the 206 gynecologic claims, 45 (22%) were indefensible because of breaches of standards of care (62%), problems with documentation (24%), or both (13%). The incidence of indefensible obstetric and gynecologic claims was 25%. Indefensible claims were analyzed to determine the common medical and surgical problems that instigated the malpractice suits. Recommendations are made that should reduce the incidence of indefensible malpractice suits. (AM J OBSTET GYNECOL 1991;165:298-306.)

Key words: Breach of standards of care, documentation, malpractice

The malpractice crisis has had significant impact on obstetricians, gynecologists, and the women who seek their services.

The 1990 American College of Obstetricians and Gynecologists (ACOG) Professional Liability Survey[1] revealed that 78% of obstetricians and gynecologists have been sued at least once; 37% have been sued three or more times. The survey also revealed that 62% stopped practicing obstetrics before the age of 55 years and that 31% discontinued obstetrics before the age of 45 years. Twenty-four percent of obstetricians have decreased their level of high-risk obstetrics.

Another survey[2] revealed that 36% of obstetric residents have been sued while in training.

The 1990 ACOG survey[1] noted that obstetric malpractice claims outnumbered gynecologic malpractice claims by 58% to 42%. In this study of 500 claims the

Table I. Analysis of 500 obstetric and gynecologic malpractice claims

				Reason indefensible						
				Breach of standards		*Lack of documentation*		*Combination*		
	No. of claims	*No. defensible*	*No indefensible*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*% Indefensible*
Obstetric	294	215	79	56	71	4	5	19	24	27
Gynecologic	206	161	45	28	62	11	24	6	13	22
TOTAL	500	376	124	84	68	15	12	25	20	25

incidence of obstetric claims was 59% and gynecologic claims 41%.

I reviewed 500 obstetric and gynecologic claims to determine the causes of the claims and the percentage of indefensible claims. The indefensible claims were further analyzed to determine whether they were indefensible because of a breach in the standards of care, lack of documentation, or both. Recommendations are made that may significantly reduce further claims.

Material and methods

Between 1983 and 1988, I reviewed 500 obstetric and gynecologic malpractice claims primarily from the southeastern United States. The 500 consecutive cases, which were supplied by several insurance companies and attorneys, are analyzed in this report.

A case was categorized as indefensible when the treatment rendered was considered to be below the degree of care generally exercised by physicians under the same or similar circumstances. This standard of care was established after consultation of the following sources and references: (1) ACOG's *Standards for Obstetric-Gynecologic Services*, editions 1 through 6; (2) *AGOC Technical Bulletins*, 1968 through 1988; (3) articles indexed in the National Library of Medicine's MEDLARS database; and (4) *ACOG Committee Opinions*, Nos. 11 through 64.

Deviation from these standards without reasonable explanation was classified as being indefensible. Methods of therapy and procedures that might be controversial but were documented as acceptable through literature searches were classified as defensible and not malpractice. A poor outcome, or "maloccurrence," was never classified as malpractice unless it resulted from a direct deviation from the established standards. In this review substandard care per se did not necessarily render a case indefensible unless a cause-and-effect relationship existed between the substandard care and the poor outcome.

Results

The 500 claims were divided into 294 obstetric claims and 206 gynecologic claims (Table I).

Of the obstetric claims, 79 (27%) were classified as indefensible. Of these, 56 (71%) breached the standards of care, 4 (5%) had inadequate documentation, and 19 (24%) had both problems.

Of the gynecologic claims, 45 (22%) were classified as indefensible. Of these, 28 (62%) breached the standards of care, 11 (24%) had inadequate documentation, and 6 (13%) had both deficiencies.

Obstetric cases. Many of the obstetric claims comprised several clinical problems, making classification difficult. These cases were categorized according to the problem that instigated the malpractice suit (Tables IIA through IID).

Several problems common to the indefensible obstetric claims involved cord-placental problems, stillbirths, presence of meconium, fetal distress, dystocia of labor, abnormal presentations other than breech, cephalopelvic disproportion, brain damage, perinatal deaths, infant trauma, and vaginal birth after cesarean section. These claims could not be defended because of failure to (1) appropriately monitor or record the fetal heart rate with auscultation or electronic fetal heart monitoring, (2) recognize and act on potentially ominous fetal heart rate tracings, (3) recognize and appropriately manage dystocia of labor, (4) administer oxytocin according to ACOG guidelines, (5) have cesarean capabilities within 30 minutes without a reasonable explanation for the delay, (6) properly resuscitate the newborn, (7) respond to nurses' calls in a timely and appropriate manner when notified of potential problems, or (8) notify a physician when a nurse midwife encountered a high-risk situation during labor.

The postmaturity claims that could not be defended were caused by problems related to the use and misuse of antepartum fetal surveillance.

The indefensible cases of shoulder dystocia were so classified because the obstetricians ignored the risk factors of maternal diabetes, obesity, and fetal macrosomia coupled with dystocia of labor.

Breech deliveries were judged to be indefensible when there was improper use of oxytocin and failure to recognize dysfunctional labor.

In the indefensible forceps–vacuum extractor cases, physicians failed to evaluate and recognize dystocia of labor and attempted midforceps procedures that resulted in significant infant morbidity.

Table IIA. Analysis of obstetric cases: Prenatal labor and delivery

Cause	*No. of claims*	*No. defensible*	*No. indefensible*	*Reason indefensible*		
				Breach of standards	*Lack of documentation*	*Combination*

Infections in newborn						
Herpes	3	3	0			
Miscellaneous	3	3	0			
Perinatal death	3	2	1		1	
Infant trauma	3	2	1			1
Respiratory distress	2	2	0			

When nurses failed to notify the physician or the physician failed to respond in a timely and appropriate manner to the obvious signs and symptoms of pregnancy-induced hypertension, the claims could not be defended.

Failure to diagnose a major congenital anomaly on a midpregnancy ultrasonogram by a physician who implied he possessed such diagnostic skills rendered one claim indefensible.

Circumcision claims became indefensible when electrocautery machines were improperly used or proper consent forms had not been signed.

In cases of abortion, indefensible claims arose from physicians' failure to adequately inform patients as to the signs and symptoms of infection, failure to recognize and appropriately treat the postoperative complications of infection resulting in serious morbidity and extensive surgery, and allowing physician's assistants to manage serious complications without adequate physician supervision.

Maternal death claims could not be defended because the physicians failed to recognize and appropriately treat sepsis; administer a general anesthetic and monitor the patient properly, resulting in an unrecognized gastric aspiration; administer oxytocin properly, resulting in hyperstimulation, abruptio placentae, and disseminated intravascular coagulation; and deliver a known high-risk obstetric patient in a hospital setting (the patient was delivered in a birthing center).

Claims related to x-ray examinations and drugs taken

Table IIC. Analysis of obstetric cases: Surgical problems

				Reason indefensible		
Cause	*No. of claims*	*No. defensible*	*No. indefensible*	*Breach of standards*	*Lack of documentation*	*Combination*

during pregnancy were classified as indefensible when there was no evidence that the physician had attempted to ascertain whether the patient was pregnant before ordering x-ray examinations or prescribing medications contraindicated in pregnancy.

Gynecologic cases. The leading gynecologic claim (Tables IIIA and IIIB) was unsatisfactory sterilization. When a physician failed to carry out a recognized surgical sterilization procedure properly and the patient became pregnant, the claim could not be defended. Failure to obtain signed consent forms for sterilization also contributed to indefensible suits.

Although injury to the genitourinary tract was the second major gynecologic malpractice claim, it accounted for the highest number of indefensible gynecologic claims. The claims were indefensible not because of the original injury but because the physician failed to recognize the signs and symptoms of the injury and therefore failed to bring about a timely repair of the injury, leading to permanent damage in two cases. Three of the claims were rendered indefensible because of lack of documentation in either the office or hospital records to justify the original surgery.

When a nurse failed to notify a physician of signs and symptoms of wound infection, or the physician failed to respond in a timely manner, the claim was judged indefensible. In one postoperative complication case, an irrigation needle was lost in the abdomen during a microsurgical procedure, resulting in an injury to the bowel and a need for further surgery.

The indefensible ectopic pregnancy claims resulted from several different problems. When the patient was initially seen with the classic signs of ectopic pregnancy and an appropriate investigation was not conducted, the case was deemed malpractice. When an elective abortion was attempted, and the tissue obtained was not diagnostic of an intrauterine gestation, and no further evaluation was conducted, the claim could not be defended.

A prolonged vaginal procedure, during which the patient was unfavorably positioned in the stirrups, resulted in bilateral foot drop and an indefensible claim of nerve injury.

Intrauterine contraceptive device (IUD) claims that could not be defended involved insertion of an IUD even though it was contraindicated for medical reasons, failure to investigate a lost IUD string, and failure to explain the potential risks of using an IUD.

Failure to diagnose breast cancer has become a more frequent claim. The cases in this series could not be defended because of physician failure to evaluate obvious breast masses with mammogram, surgical con-

sultation, or both; failure to follow up on a suspicious mammogram report; and failure to perform a breast examination during the patient's annual physical examination.

The improper management of cervical pathologic findings noted on Papanicolaou smears led to claims of malpractice. When the pathologist suggested or the findings of the Papanicolaou smear warranted colposcopic examination and it was not performed, the defense of invasive cancers of the cervix was impossible.

The miscellaneous indefensible medical problem involved the misfiling of a laboratory report by office personnel. The physician did not discover that a patient had had positive test results for gonorrhea until after a full-blown case of pelvic inflammatory disease developed. The physician was held liable for the error.

Comment

This review confirms that documentation is a significant problem in medical recordkeeping. Twenty-four percent of the gynecologic cases and 5% of the obstetric cases were found indefensible solely because of failure to document records in a complete and contemporaneous manner. Failure to document records adequately was an important factor in another 24% of obstetric cases and 13% of gynecologic cases (Table I). In a courtroom the finest care rendered under the best circumstances may be difficult or impossible to defend if it is not documented. An altered record also will make a case impossible to defend. In front of a jury a physician's credibility can easily be destroyed.

When faced with a difficult obstetric or gynecologic problem, a physician should write out a plan of therapy or get consultation. It is easier to defend the judgment of two physicians even if the outcome is bad. Juries generally accept such judgments over those of experts who never attended the patient. It must be stressed that judgmental decisions, even if they result in maloccurrence, are defensible and do not constitute malpractice.

Several specific areas in the obstetric cases need to be addressed. Oxytocin was frequently a primary or contributing factor in the obstetric malpractice claims. The *ACOG Standards for Obstetric-Gynecologic Services* and the *ACOG Technical Bulletin* No. 110, offer quite specific guidelines that, if followed, would have made many claims defensible.

At its best, electronic fetal heart monitoring has serious limitations.[3-5] In this study the major problems relating to the electronic fetal heart monitor were failure to recognize and properly classify decelerations, respond to calls from nurses concerning potentially ominous patterns, form a resonable management plan when potentially ominous patterns were observed, and obtain a reasonably acceptable or readable tracing.

Two cases in this retrospective analysis were claims involving infants with neurologic impairments that were successfully defended by evidence gained through examination of the cord and placenta. Recent research[6]

Table IIIB. Analysis of gynecologic cases: Medical

Cause	No. of claims	No. defensible	No. indefensible	Reason indefensible: Breach of standards	Reason indefensible: Lack of documentation	Reason indefensible: Combination
IUD	11	6	5	5		
Failure to diagnose breast cancer	9	5	4	4		
Pelvic inflammatory disease	7	5	2	1		1
Management of cervical pathologic findings	3	1	2	2		
Management of endometriosis	3	3	0			
Medical errors	2	1	1	1		
Management of human papillomavirus infections	1	1	0			
Miscellaneous medical problems	11	10	1	1		

has demonstrated that neurologic impairment in an infant is not prima facie evidence of substandard care or negligence by the obstetrician at birth. Rather, pathologic conditions of the cord and placenta are increasingly recognized as the major cause of neurologic impairment.[7] These conditions often develop during the prenatal period long before labor and delivery; although they cannot be prevented by the best of obstetric care, they can be identified by examining the placenta.

If there is a maternal, fetal-newborn, or placenta–umbilical cord condition that warrants study (Table IV), the attending physician should arrange for a placental examination. If the pathologist is not well versed in placental pathology, he or she can still help by recording measurements, taking photographs, and making slides that can be reviewed by a placental pathologist. Placental examination often reveals the cause of preterm labor, premature rupture of the membranes, intrauterine growth retardation, and antenatal hypoxia.

Failure to recognize dystocia of labor was a complicating factor in several indefensible claims. Labor records that use the Friedman curve[8] would facilitate early recognition of the problem.

Before medication contraindicated in pregnancy is prescribed or x-ray studies to evaluate gastrointestinal complaints are ordered, it is sensible to at least list the patient's last menstrual period. If a question of pregnancy exists, it is imperative to test the patient for pregnancy before taking further action.

Sterilization failures accounted for the largest number of gynecologic malpractice claims. The majority of these claims might have been prevented if the physician had given the patient printed material, such as an ACOG pamphlet on sterilization, that outlines the risks, complications, and failure rate of sterilization procedures. It should be stressed that pregnancy can occur after the procedure, and it should be documented in the patient's chart that this information was given and discussed.

Table IV. Indications for placental examination

- Maternal
  - Diabetes mellitus
  - Pregnancy-induced hypertension
  - Premature rupture of the membranes
  - Preterm delivery (<36 weeks)
  - Postterm delivery (>42 weeks)
  - Unexplained fever
  - Poor obstetric history
  - History of drug use or abuse
- Fetus-newborn
  - Stillborn
  - Neonatal death
  - Multiple gestation
  - Intrauterine growth retardation
  - Congenital anomalies
  - Erythroblastosis fetalis
  - Transfer to neonatal intensive care unit
  - Ominous fetal heart tracing
  - Presence of meconium
  - Apgar score <5 at 1 min; <7 at 5 min
- Placental–umbilical cord
  - Infarction
  - Abruptio placentae
  - Vasa previa
  - Placenta previa
  - Abnormal calcification
  - Abnormal appearance of placenta or umbilical cord

Injuries to the genitourinary tract accounted for the second highest number of gynecologic cases; more important, they accounted for the highest number of indefensible cases. Injury to the ureter or bladder is an acknowledged risk of obstetric or gynecologic surgery. The frequency of ureteral injuries has been quoted by various authors to range from 0.1% to 30%.[9, 10] In this review the indefensible claims were caused by physician failure to respond in a timely and appropriate manner to the patient's signs and symptoms. When a surgeon promptly undertakes an evaluation of a suspected injury to the lower genitourinary tract, the defense is generally quite easy.

With the increased incidence of ectopic pregnancy in the last decade and the considerable maternal morbidity and mortality that accompany it, physicians must keep this diagnosis in the forefront of their differential diagnoses when confronted with a patient with abdominal pain, amenorrhea, and abnormal vaginal bleeding. The refinement of both urinary and serum pregnancy tests, coupled with the improvement in diagnostic ultrasonography, will aid in early diagnosis. Weckstein et al.[11] achieved an unruptured ectopic diagnostic rate of 27% with this approach.

Failure to diagnose breast cancer has recently become a rising cause of malpractice claims. Because many women consider their obstetrician-gynecologists to be their primary care physicians, a structured management plan is recommended. Breast cancer develops in 1 in 11 women[12]; the incidence of this disease is almost twice that of all gynecologic cancers combined. Physicians should encourage and teach patients breast self-examination at an early age. In this study breast cancer developed in four patients under 35 years of age and in one at 25 years of age.

The American Cancer Society[13] has made the following recommendations with regard to mammography: a baseline examination at 35 years of age, an examination every 2 years in the 40s, and annual examinations from 50 years of age. When a discrete mass or change in the breast is found by the patient or her physician, it is appropriate to reexamine the patient after her next menstrual period. If the suspicious area is still present, a mammogram should be taken. Even if the mammogram is normal, the patient should be referred for surgical consultation because the true-positive rate for mammography varies from 82% to 95.7%, according to studies by Holland et al.[14] This protocol makes claims for failure to diagnose breast cancer very defensible.

Human papillomavirus is not considered to be a likely cause of cervical cancer,[15] even though Koch's postulates have not been fulfilled. The early identification and eradication of infections with this virus should result in a decrease in cervical cancer. Colposcopic evaluation[16] of the cervix and lower genital tract in cases of abnormal Papanicolaou smears has proved to be beneficial to patients.

In conclusion, this analysis of 500 obstetric and gynecologic malpractice claims found an overall incidence of malpractice of 25%. This study did not confirm the popular public opinion that malpractice occurs because of a few bad physicians. Rather, a varied group of physicians, from professors at universities to board-certified obstetricians and gynecologists practicing a modern, well-equipped centers to physicians in rural level I hospitals, were all involved in malpractice claims. There were very few repeat offenders. Had the guidelines discussed in this study been followed, the majority of indefensible cases would have been defensible and the unfavorable outcomes might have been prevented.

Discussion

DR. WILLIAM H. KIRKLEY, Fort Lauderdale, Florida. I feel a bit uneasy when someone states that a case is indefensible. There are too many variables, such as the defending attorney (extremely important), the quality of the records, and the defendant (will he or she make a good witness?). Many cases are settled because the defense attorney realizes it would be a disaster to place the defendant on the stand. Last, but not the only factor, is what happened. (I agree that if during circumcision you burn the head of the penis off, this is indefensible.) I read a report published by an insurance carrier that had several hundred cases reviewed by obstetrician-gynecologists in an academic setting. They found that malpractice occurred in >70% of the cases. Dr. Ward found 27% in obstetrics and 22% in gynecology. In several hundred cases reviewed I believed 10% to be indefensible. (I asked Dr. Ward if he could get 25 cases he believed to be indefensible and let me review them. Unfortunately, this was not possible.) The hardest decisions I have had to make involved whether to testify on behalf of the defendant in cases that I believed not to have been handled properly but that I believed to be defensible. I am sure everyone agrees that the expert witness's opinion is not necessarily the generally accepted standard of care. Dr. Ward used ACOG's *Standards*, with which we are all familiar. This makes me very nervous! Please let's not have a format or outline so that any deviation is detectable as malpractice by an attorney. ACOG never intended, and should not have, for this to be *the* standard of care; it is *a* standard of care. On numerous occasions I have testified that ACOG bulletins are merely the opinion of the four or five people on that committee. If you posed the circumstances of a trial to the 20,000 to 30,000 members of ACOG who actually establish the standard of care in their localities, you would get a diversity of opinions. Never let an article, book, or bulletin establish the standard of care (all ACOG publications carry this disclaimer).

I agree with Dr. Ward that poor records are a major problem. I believe they are *the* major problem. He noted that the records were so poor in 5% of the obstetrics cases that this alone mandated settlement; in 24% poor records were a strong contributing factor to the resolution. In gynecology 24% of the physicians failed to keep adequate records; in 13% inadequate records contributed to the outcome. Remember, even in the cases that go to trial, poor records may be a problem in your defense. George Hart of Atlanta, probably the best defending attorney in the country in cases involving brain damage, told me that the physicians in 75% of his cases had serious record-keeping problems.

Dr. Ward superifically passes over some problems that I am unable to comment on. I am sure time was a factor, but he probably couldn't be too specific because some cases may still be in litigation.

X-ray examinations and drugs taken during pregnancy should in general not be too hard to defend because they almost never cause a problem.

With ultrasonography and β-subunit human chorionic gonadotropin, ectopic pregnancy can be detected earlier. Failure to do so would be hard to defend, but not impossible.

If failure to investigate a lost IUD string is malpractice, I am guilty.

Contrary to Dr. Ward's findings in these 500 cases, missed breast cancer is the leading claim against gynecologists. If a simple protocol is adhered to, 99% of these cases will be eliminated. I presented this protocol at a District IV malpractice seminar that Gluck and I conducted in Baltimore 5 to 6 years ago. Had this protocol been followed, there would not be a problem today.

Does Dr. Ward believe it is malpractice to treat suspected or documented pelvic inflammatory disease without tuboovarian abscess on an outpatient basis, or does he believe that all patients should be admitted to the hosptial for thorough workups and be given multiple intravenous antibiotic therapy. Would the fact that the woman did not want children alter his opinion?

I have observed mismanagement of carcinoma of the cervix. One case I was involved in was amazing. For 2 years in a row an abnormal Papanicolaou smear, reported to be class II, "probably inflammatory," was ignored. The third year a lesion of the cervix was recorded. The fourth year advanced carcinoma of the cervix was observed. With so many physicians doing colposcopy, I am afraid that missed cervical cancer will be the lawyers' next big push.

Dr. Ward correctly advises us not to alter records. With duplicating machines widely available, you haven't a chance. I am amazed that I still see this happening. The most recent case was detected because the defendant's office personnel had sent records to the plaintiff's attorney before the chart was altered. Good communication with the patient and the family is important, as Dr. Ward points out very clearly. But, handle it properly. Be sure a nurse is with you; preferably talk with the patient and only one family member. After you have completed this talk, immediately write a note stating exactly what you told the patient and have the nurse cosign the note. The 10 or 15 minutes it takes to write this note may save you many hours in the courtroom and millions of dollars.

I believe it is difficult to be so dogmatic about so-called indefensible claims of error in monitoring and interpreting fetal tracings. I remember that 8 to 10 years ago 12 to 15 physicians were asked to review a number of electronic fetal heart monitor strips and were asked to give a diagnosis and prognosis. They agreed in only two or three cases! If the experts can't agree, how can we be so critical as to accuse a person of malpractice from a tracing. I strongly suggest that when an electronic fetal heart monitor strip is abnormal, note your awareness of this, your interpretation of it, and your course of treatment. Better still, as Dr. Ward suggests, have another physician consult with you and document the consultation.

I am surprised that improper management of a dystocia was an indefensible problem. I thought that at any suggestion of dystocia nowadays a cesarean section is performed. I would ask Dr. Ward if this was not done.

Postmaturity syndrome is so controversial and the protocol is so varied from institution to institution that I do not believe that the majority of the 15,000 to 20,000 ACOG members, particularly those practicing in small communities at level I facilities, will agree with the management proposed by our academic community.

As for the prolonged vaginal procedure during which the patient was unfavorably positioned in stirrups that resulted in foot drop, I ask Dr. Ward how he arrived at the idea of an unfavorable position. Or was the attending physician crazier than I think he was? This brings up a very important point: Never tell a patient or plaintiff's attorney you did wrong. I remember a physician doing this when he had done nothing wrong.

Dr. Alton V. Hallum, Jr., Atlanta, Georgia. How do you educate your pathologists who are not up to date, and how do you use those slides at a later date?

Dr. Murray A. Freedman, Augusta, Georgia. It is sad that we continue to treat the things that result from the liability crisis—rather than the cause, which lies in the fact that it is so terribly lucrative to one other profession.

Dr. Mary E. Blanchard, Sumter, South Carolina. We can tell all the lawyer jokes that we want to, but as Pogo says, "We have met the enemy, and the enemy is us." No lawyer can get any medical malpractice case to court at any time without a medical expert. As long as we have medical experts stating that the patient had an enema and that this caused the baby to be brain damaged, we are in deep trouble. I have been involved in litigation in which there were two experts from two "outstanding institutions" in this country. I called the chairperson of a department and he more or less told me that he was hired at that university with the proviso that a certain physician could continue to testify about anything that he wanted to testify about. The second physician, a friend of mine at a major institution, said that he felt bad that a member of his department was saying what he was saying. Sooner or later we have to take a stand with these people. Unless we do, we will continue to find ourselves in the crisis we are in.

Dr. Hugo S. Moreno, East Point, Georgia. Considering that the National Data Bank requests that any award or settlement above $100,000 be registered in the physician's name, do you think that this will increase the number of frivolous suits that go to court regardless of merit?

Dr. J. Greg Johnson, Greenville, South Carolina. Do you think that umbilical cord gas pH is an acceptable substitute for placental pathology because it is difficult to get pathologists to look at the placenta? What do you think of the routine use of umbilical cord gas pH?

Dr. Ward (Closing). I encourage the use of umbilical cord blood gas studies in all cesarean deliveries and in those infants delivered vaginally who have low Apgar scores. Umbilical cord blood gas studies do not replace placental examinations. One method of educating pathologists is to give them copies of the article by Naeye (see reference 6 of article). If pathologists are not knowledgeable about the placenta, they can still prepare slides of the placenta. These slides can be reviewed at a later date by a placental pathologist.

There is concern that more lawsuits will be defended to avoid the settlement-reporting requirements of the National Data Bank. This could ultimately result in an increase in malpractice premiums.

count six

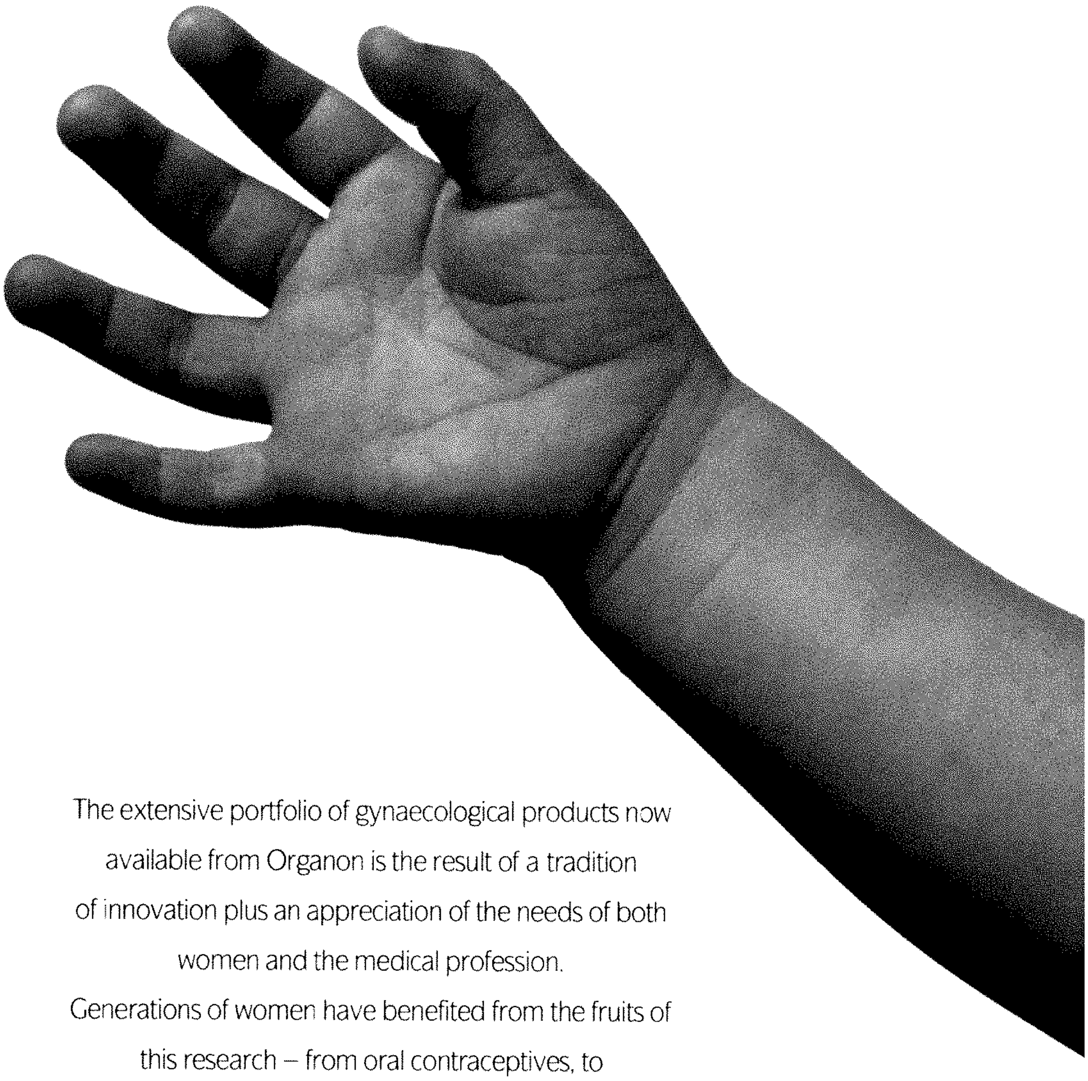
The innovative efforts made by Organon in gynaecology are making such headway that its broad product portfolio now approaches completeness:

1 oral contraceptives
2 hormone replacement therapy
3 gynaecological disorders
4 obstetrics
5 fertility stimulation
6 diagnostics

ORGANON IN GYNAECOLOGY

striving for completeness

Organon



the human signature

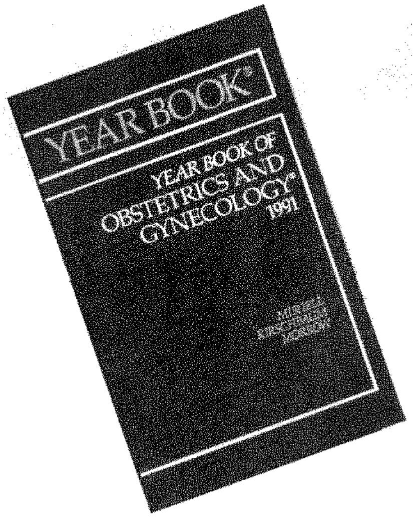
The extensive portfolio of gynaecological products now available from Organon is the result of a tradition of innovation plus an appreciation of the needs of both women and the medical profession.
Generations of women have benefited from the fruits of this research – from oral contraceptives, to hormone replacement therapy and gonadotrophins. Organon's fertility stimulating products have for generations been relied upon throughout the world.
Living proof of Organon's commitment to worldwide gynaecological service.

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

Modern medicine's answer to normal memory loss.



A lively and authoritative review of the year's best journal literature.

Let's face it. Remembering everything from the hundreds of articles you read is a herculean task. You're bound to forget a few important details. It's normal. It's healthy. But with a subscription to the *Year Book of Obstetrics and Gynecology*, it's also unnecessary.

Each year, the *Year Book of Obstetrics and Gynecology* brings you the most important articles relating to obstetrics and gynecology. The articles, chosen by our distinguished editors, are abstracted into concise one and two page summaries for quick and efficient reading. Nearly every article is accompanied by personal commentary from the editors discussing its significance to your daily practice.

The *Year Book of Obstetrics and Gynecology*— it's the best way to remember what you shouldn't forget.

☐ **Yes! I want an overview of the year's most important journal literature.**
Please send my **30-day FREE examination** copy of the *1991 Year Book of Obstetrics and Gynecology* (22118) by Daniel R. Mishell, Jr. If I decide to keep the book I'll pay $57.95 plus shipping and handling.

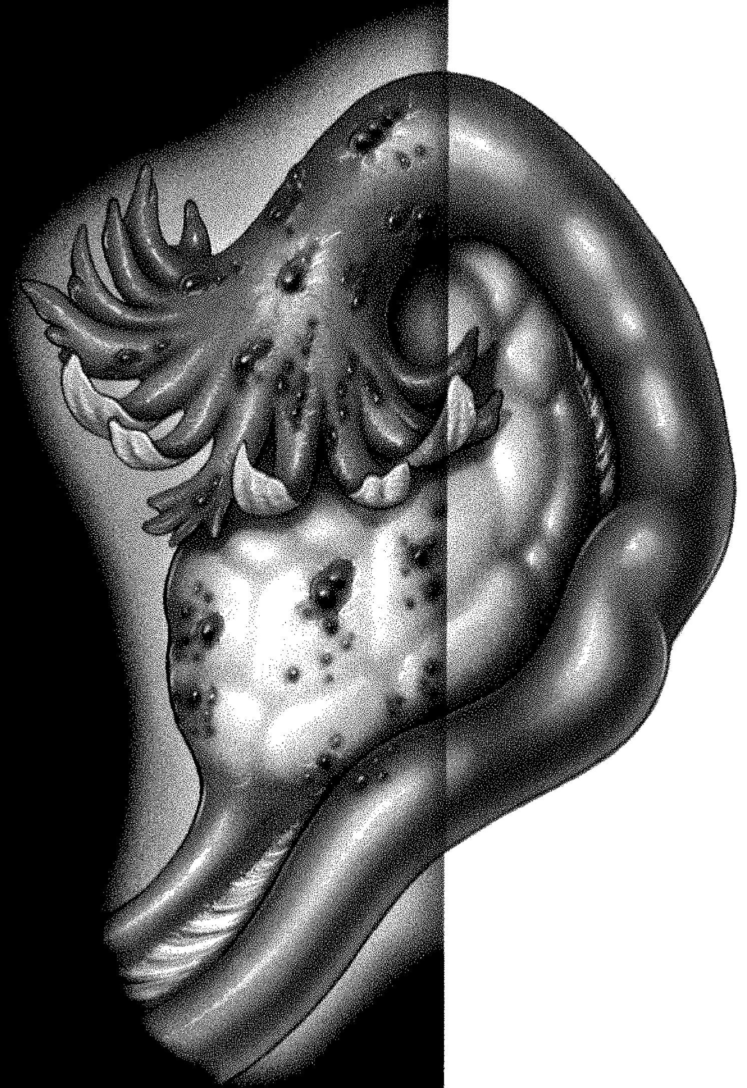
When you purchase a Year Book, we'll also send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you d not want the Year Book, the advance notice makes it easy for you to let us know. And if you elect to receive the new Year Book, you need do nothing. We will send it on publication. No worry. No wasted motion. And, of course, ever Year Book is yours to examine *free of charge* for 30 days.

IN THE MANAGEMENT

OF ENDOMETRIOSIS

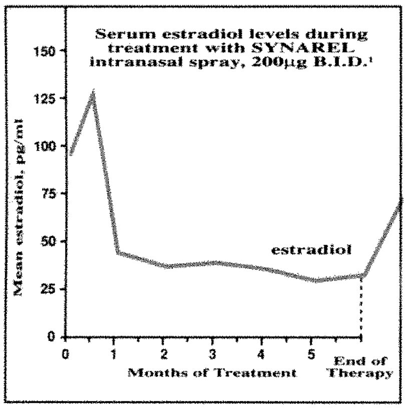


nough is enough

Insufficient estradiol suppression may not resolve the symptoms of endometriosis. Excessive suppression may create additional problems for your patients.
SYNAREL intranasal spray promises no less than you need – and no more than you want.

Power to suppress estradiol to levels that result in effective relief

SYNAREL intranasal spray, 200μg B.I.D., lowers serum estradiol to near menopausal levels within approximately 1 month—and maintains those levels throughout the 6-month course of therapy.* As a result, 92% of patients (n=143) taking SYNAREL were symptom-free or had only mild symptoms following a 6-month course of therapy. And, of the 60% of patients (n=110) who had complete relief of symptoms, 83% remained symptom-free or experienced only mild symptoms 6 months after treatment with SYNAREL was discontinued. Retreatment cannot be recommended since safety data for retreatment are not currently available.



Control in the management of hypoestrogenic and therapeutic effects

SYNAREL produces minimal impact on bone, as well as a predictable and manageable hypoestrogenic profile. What's more, SYNAREL lets you terminate treatment immediately should that be required for any reason—unlike the depot form of GnRH† therapy. In fact, drug clearance with SYNAREL usually occurs within 24 hours.[2]

Bone density changes during and after treatment with SYNAREL intranasal spray, 400 μg/day [Percent changes from baseline]

Site Method Units	Time of Study Baseline	End of Treatment	Post-treatment
Lumbar Vertebrae QCT* integral (g/vertebrae) n=21	13.4	12.8 −4.3%	13.1 −3.3%
Trabecular Bone of Vertebrae QCT* (mg/cc) n=23	161.3	147.6 −8.7%	152.0 −4.9%
Lumbar Vertebrae DPA† (g/cm²) n=6	0.98	0.93 −5.9%	0.96 −1.4%
Distal Radius SPA‡ (Units) n=6	40.2	39.5 −1.6%	39.6 −0.8%

*Quantitative computed tomography ‡Single photon absorptiometry
†Dual photon absorptiometry

SYNAREL is also well tolerated, with a low incidence of nasal irritation (10%). And, since SYNAREL lowers estrogen without adding androgens, it helps you avoid potentially irreversible androgenic effects. (The most frequent side effects are those associated with hypoestrogenism.)

In the management of endometriosis, only SYNAREL can balance the power you need with the control you want in a unique intranasal spray. For more information, please call 1-800-727-0400.

---

*Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.
†Gonadotropin-releasing hormone analog.

Committed to the OB/GYN and women's healthcare

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.
INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.
CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.
WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.
When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.
PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve spontaneously or may require drug discontinuation or surgery.
Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the dose. Counsel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients. 3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician. 4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content. 6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption. 7. Retreatment cannot be recommended since safety data beyond 6 months are not available.
Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.
Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.
Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.
Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.
Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.
Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.
Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.
Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.
Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.
Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.
OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

CURRENT PROBLEMS IN
OBSTETRICS, GYNECOLOG
AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your speci and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagno and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecolog and more.
- Authors are selected for their expertise; you'll be from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Changes in lipids and lipoproteins with long-term estrogen deficiency and hormone replacement therapy

R. Don Gambrell, Jr., MD,[a] and Ana-Zully Teran, MD[b]
Augusta, Georgia

Cross-sectional data of the long-term effects of estrogens, androgens, and progestogens on lipids and lipoproteins were obtained in 556 postmenopausal women aged 24 to 85 years with follow-up for 1 to 44 years. Baseline values were obtained in 155 women from <1 year up to 30 years after menopause. Total cholesterol and low-density lipoprotein cholesterol tended to rise during the early postmenopausal years while high-density lipoprotein cholesterol did not change. Triglycerides were related to weight and were significantly different only between untreated women of normal weight (128.3 ± 7.80 mg/dl) and hormone users weighing >200 pounds (252.9 ± 9.44 mg/dl), $p \leq 0.001$. Although mean high-density lipoprotein cholesterol was lower with both C-21 progestogens (64.5 ± 4.16 mg/dl) and C-19 progestogens (61.9 ± 3.84 mg/dl), there were no statistically significant differences on comparison with levels in the unopposed estrogen users (67.0 ± 3.94 mg/dl). Smoking significantly depressed high-density lipoprotein cholesterol in both hormone users ($p \leq 0.001$) and untreated women ($p \leq 0.001$). Added progestogens do not adversely affect lipids and lipoproteins over the long term when adequate dosages of estrogens are used. (AM J OBSTET GYNECOL 1991;165:307-17.)

Key words: Progestogens, androgens, estrogens, lipids, lipoproteins

One of the greatest benefits that will accrue to postmenopausal estrogen users will be the prevention of cardiovascular disease.[1-9] With most types, dosages, and routes of administration, serum lipid patterns improve, primarily by a reduction in total cholesterol and low-density lipoprotein (LDL) cholesterol with an increase in high-density lipoprotein (HDL) cholesterol, thus improving the LDL/HDL ratio. Concern has been expressed that added progestogens to estrogen replacement therapy regimens may adversely affect the estrogen-induced beneficial effects on lipids, thus negating the benefit of hormone replacement on heart disease. Most of this is based on short-term studies of estrogen-progestogen use and speculation from old oral contraceptive data that postmenopausal hormone therapy will have similar effects.[10, 11] Although HDL cholesterol levels do not change with estrogen deficiency, LDL cholesterol and total cholesterol may increase. Estrogen therapy may increase HDL cholesterol while decreasing total cholesterol, primarily by decreasing LDL cholesterol.[12]

What is most important is not the short-term effects since most women will receive hormone replacement for many years. Previously published from our institution was a prospective intermediate-term study of a standard dosage of estrogen and comparison of the effects of three different progestogens on lipoproteins over a 6- to 18-month period.[13] Patients have received hormone replacement therapy for >50 years at the Medical College of Georgia. Cross-sectional data of the really long-term effects of estrogens, androgens, and progestogens on lipids and lipoproteins constitute the basis for this report.

Material and methods

There were 556 postmenopausal women who had been seen within the previous 6 months so that current status was known. Their ages ranged from 24 to 85 years with a mean of 57.14 ± 10.56 years. (The 24-year-old patient had androgen insensitivity syndrome with gonads removed at age 2 years; she has received hormone replacement for 12 years.) Hormone replacement has been given to these women for 1 to 44 years with a mean duration of therapy of 11.97 ± 8.11 years. Unopposed estrogen and/or androgen therapy, mostly in the form of pellet implants, was given to 132 of these patients whereas 424 also received progestogens. Baseline values of lipids and lipoproteins before hormone replacement were taken from <1 year up to 30 years after menopause in 155 of these 556 patients. In addition to measuring total cholesterol and triglycerides, fractionation of the lipoproteins was performed by electrophoresis into HDL, very LDL (VLDL), and LDL cholesterol with an interassay coefficient of variation of

6/6/30761

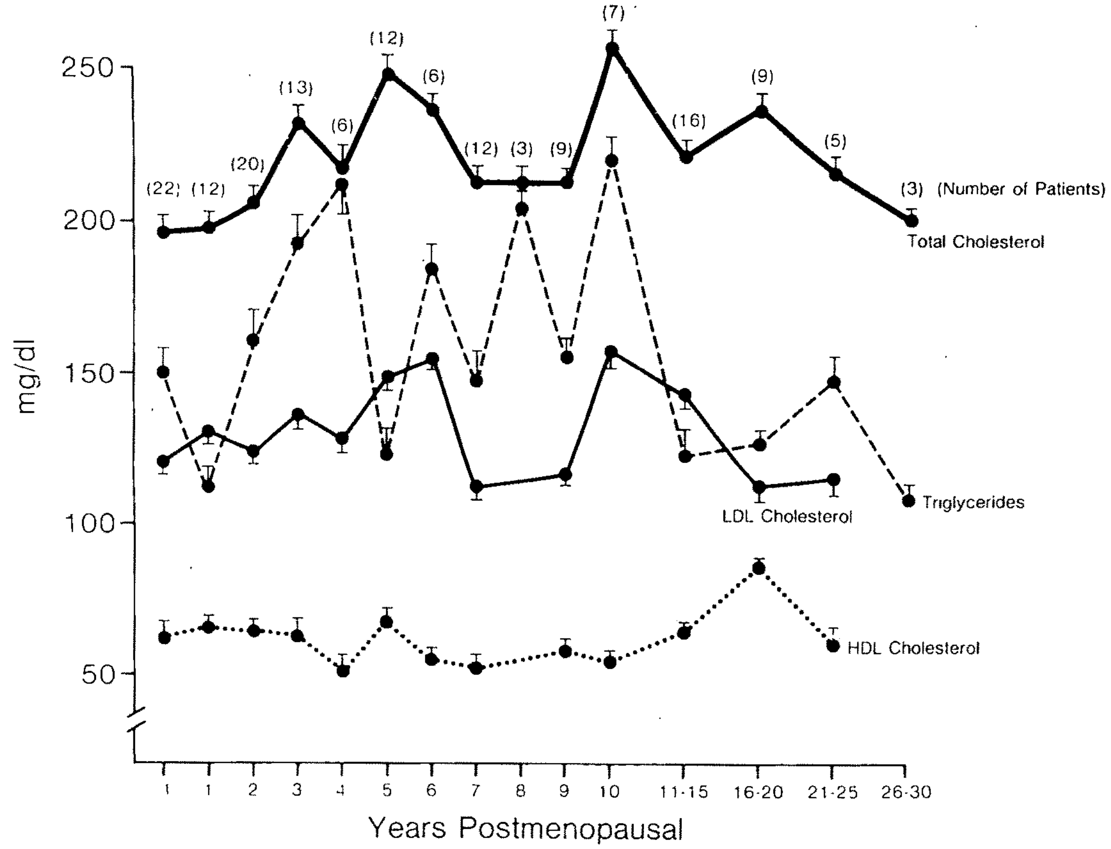

Fig. 1. Mean values of total cholesterol, triglycerides, LDL cholesterol, and HDL cholesterol at baseline before hormone replacement therapy in 155 women from <1 year up to 30 years after the last menstrual period. All values are expressed as mean ± SE. Number of patients at each year is shown in parentheses.

±3.5%. Hormone replacement therapy was given in various combinations but mostly with subcutaneous implantation of 25 mg estradiol pellets and 75 mg testosterone pellets every 4 to 6 months. The subgroups of hormone users were heterogeneous, but 494 women (88.8%) were treated with subcutaneous pellets whereas 404 patients (72.7%) received one or two pellets of estradiol and one or two pellets of testosterone. C-21 progestogens used included 2.5 to 10 mg medroxyprogesterone acetate, 25 to 100 mg progesterone suppositories, and 100 to 300 mg micronized progesterone daily by mouth for 10 to 13 days each month or menstrual cycle. C-19 progestogens used were 2.5 to 5 mg of norethindrone acetate, 2.5 to 5 mg of norethindrone, and 0.075 to 0.150 mg of norgestrel. Most patients were given cyclic progestogen therapy although a few used continuous progestogens. Oral estrogens, including 0.625 to 1.25 mg conjugated estrogens, 1 to 2 mg micronized estradiol, 1.25 to 2.5 mg estropipate, and 0.625 to 1.25 mg esterified estrogens, were given to a few patients. A few patients also used oral estrogen-androgen combinations, either 0.625 mg esterified estrogens and 1.25 mg methyltestosterone or 1.25 mg esterified estrogens and 2.5 mg methyltestosterone, and a few patients were treated with 0.05 to 0.1 mg transdermal estradiol. Statistical analysis of the data was performed by the two-way analysis of variance.

Results

Fig. 1 indicates the baseline values before hormone replacement in 155 of the 556 patients from <1 to 30 years after menopause. Values are expressed as mean + SEM. Total cholesterol tended to rise from <200 mg/dl in the early postmenopausal years to a mean of 248.2 ± 7.21 mg/dl at 5 years after the last menstrual period. LDL cholesterol also tended to increase from a mean of 120.3 ± 4.15 mg/dl in the first year after menopause to 155.0 ± 3.16 mg/dl at 6 years. Triglycerides were most variable, ranging from 114.2 ± 5.44 mg/dl at 1 year to 213.0 ± 10.34 mg/dl at 4 years. Triglycerides continued to fluctuate until more than 10 years after menopause when values ranged from 124.5 ± 6.97 to 148.4 ± 7.21 mg/dl. HDL cholesterol did not change appreciably with long-term estrogen deficiency. Mean values of HDL cholesterol ranged from 65 to 75 mg/dl throughout the early

postmenopausal years with a mean of 55.7 ± 1.70 mg/dl at 10 years after menopause.

Fig. 2 compares lipid and lipoprotein levels in the unopposed estrogen and/or androgen users with those of the estrogen-androgen-progestogen users during 1 to >36 years of hormone replacement. Total cholesterol levels ranged from 193.2 ± 5.42 to 213.3 ± 6.69 mg/dl during the first 5 years of hormone therapy including progestogens compared with a range of 193.0 ± 5.60 to 228.3 ± 4.55 mg/dl in the unopposed hormone users. After 20 years of hormone replacement, total cholesterol ranged from 191.3 ± 3.90 to 212.5 ± 5.68 mg/dl in hormone users including progestogens compared with 211.3 ± 6.97 to 233.6 ± 7.01 mg/dl in the unopposed hormone users. Overall, total cholesterol was >240 mg/dl in 21.9% of the unopposed hormone users and 11.8% of the estrogen-progestogen users. LDL cholesterol ranged from 109.4 ± 4.61 mg/dl at 2 years of estrogen-progestogen therapy to 129.3 ± 5.73 between 21 and 25 years. In the unopposed estrogen-androgen users, mean LDL cholesterol varied from 100.8 ± 3.48 mg/dl at 4 years of therapy to 164.7 ± 8.43 mg/dl between 26 and 30 years of treatment. Overall, 23.1% of the estrogen users had LDL levels >138 mg/dl as did 17.1% of the estrogen-progestogen users. Mean HDL cholesterol varied from 57.3 ± 2.99 to 69.4 ± 3.69 mg/dl with up to 36 years of estrogen-progestogen use. In the unopposed estrogen group mean HDL varied from 56.0 ± 2.88 to 73.8 ± 4.10 mg/dl over the long term. Where 78.6% of the estrogen users had HDL values >54 mg/ml, as did 69.7% of the estrogen-progestogen users, only 14.3% of the estrogen users and 17.1% of the estrogen-progestogen users had HDL values <50 mg/dl.

Lipid profiles in the unopposed estrogen-androgen users are given in Table I; they are listed by groups according to the combination of therapy. The highest mean cholesterol level in the pellet implant groups (228.8 ± 5.09 mg/dl) was observed in those women receiving 50 to 75 mg estradiol. This group also had a high mean HDL value (75.0 ± 3.64 mg/dl) so that the total cholesterol/HDL ratio was 3.47 ± 1.00, which was below average risk for heart disease (4.44 mg/dl) for our laboratory. In fact, the mean total cholesterol/HDL ratios were below average risk for heart disease in all groups, and only 7.7% of the unopposed estrogen users and 7.9% of the estrogen-progestogen users had total cholesterol/HDL ratios that were above average risk for heart disease. The highest mean cholesterol value (242.1 ± 5.13 mg/dl) was in the high-dosage oral estrogen users (1.25 mg conjugated estrogens and 2 mg micronized estradiol or 2.5 mg estropipate); however, these women also had an HDL level of 73.3 ± 3.00 mg/dl, so their total cholesterol/HDL ratio was below average risk at 3.34 ± 0.68. Even though the LDL cholesterol mean was elevated above normal (86 to 138 mg/dl) in the patients receiving 150 mg testosterone

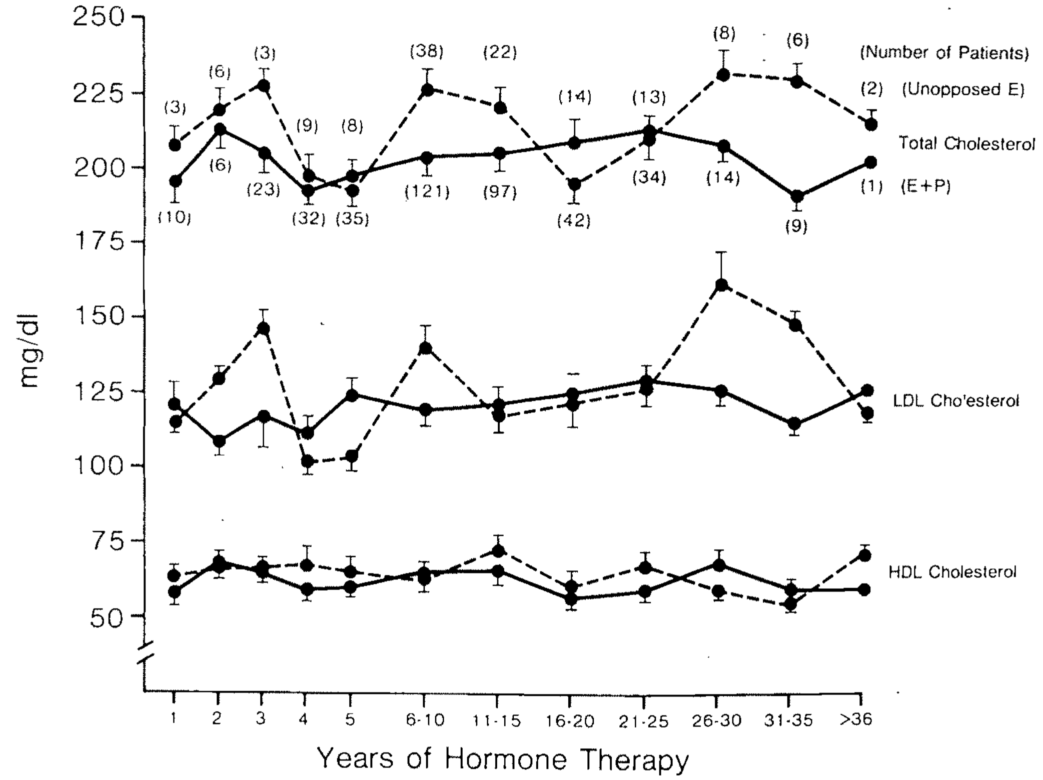

Fig. 2. Mean values of total cholesterol, LDL cholesterol, and HDL cholesterol compared in unopposed estrogen users *(Unopposed E)* and estrogen-progestogen users *(E + P)* at 1 to 44 years of hormone replacement therapy. All values are expressed as mean ± SE. Number of patients at each year is shown in parentheses. Dotted lines with *numbers above graph* represent unopposed estrogen users and *solid lines* with *numbers below graph* represent estrogen-progestogen users.

and 25 mg estradiol at 146.0 ± 6.73 mg/dl, LDL/HDL ratios in these women were below average risk for heart disease (3.22) at 2.68 ± 1.12. In fact the LDL/HDL ratio was below average risk for all groups of unopposed estrogen-androgen users.

The lipid profiles for women receiving estrogens, androgens, and C-21 progestogens are listed in Table II. Mean total cholesterol levels for all groups were close to or below 200 mg/dl, which is ideal. Mean triglyceride levels were above normal (30 to 150 mg/dl) in two groups, those receiving 150 mg testosterone and 25 mg estradiol and those receiving 75 mg estradiol and 75 mg testosterone. Mean HDL cholesterol values for all groups were in the average-risk (54 to 59 mg/dl) to low-risk (59 to 74 mg/dl) range for cardiovascular disease. In both of the oral estrogen–C-21 progestogen groups, mean HDL cholesterol levels were in the very-low-risk range (>74 mg/dl) for heart disease. Mean LDL cholesterol values were well within the normal range (86 to 138 mg/dl). The total cholesterol/HDL ratios were all well below the 4.44 ratio for average risk. In fact, several groups were below the 1/2 average risk ratio (3.27). LDL/HDL ratios all were below the average risk ratio (3.22), some approaching the 1/2 average risk ratio (1.47).

Lipid profiles for women being treated with hormone replacement including C-19 progestogens are shown in Table III. All of the mean total cholesterol values were near the ideal range of ≤200 mg/dl. Triglycerides were elevated in the groups receiving a predominance of estrogen: 75 mg estradiol and 75 mg testosterone, 50 to 75 mg estradiol, and low-dosage oral estrogen. Mean HDL levels were within the average-risk range except in the two patients being treated with 75 mg testosterone, 25 mg estradiol, and C-19 progestogens. The HDL levels were 44 and 48 mg/dl, but with both having total cholesterol levels <200, the total cholesterol/HDL ratios were 4.44 and 3.79, respectively. Mean LDL cholesterol levels were normal for all groups, including the one receiving 150 mg testosterone and C-19 progestogen. Mean total cholesterol/HDL ratios and LDL/HDL ratios were below average risk for cardiovascular disease in all groups. Overall, total cholesterol/HDL ratios were above average risk for cardiovascular disease in 7.7% of the unopposed estrogen users and 7.9% of the estrogen-progestogen users. LDL/HDL ratios were above average risk in 7.1% of the unopposed estrogen users and 3.9% of the progestogen users.

In comparing HDL cholesterol values in the unop-

150 mg Testosterone	3	184.7 ± 2.65	126.3 ± 2.24	77.0 ± 4.58	120.0 ± 5.26	3.21 ± 0.96	1.90 ± 0.92
Low oral estrogen	14	221.4 ± 6.73	121.8 ± 5.94	83.4 ± 3.70	125.9 ± 5.88	3.20 ± 0.92	1.87 ± 0.83
High oral estrogen	7	213.7 ± 5.42	146.1 ± 7.44	79.2 ± 4.07	116.8 ± 4.87	2.75 ± 0.63	1.53 ± 0.62
Oral estrogen plus testosterone	12	208.8 ± 5.38	100.8 ± 5.32	61.2 ± 3.78	130.4 ± 5.35	3.75 ± 0.99	2.35 ± 0.85
TOTAL	241	204.0 ± 5.87	144.1 ± 8.68	64.5 ± 4.16	121.8 ± 5.34	3.50 ± 1.01	2.10 ± 0.88

posed estrogen-androgen users with those in women who also received progestogens, mean values were higher in the unopposed estrogen users (67.0 ± 3.94 mg/dl) than in those with added C-21 progestogens (64.5 ± 4.16 mg/dl) or C-19 progestogens (61.9 ± 3.84 mg/dl) (Tables I, II, and III). These mean values were above the average-risk range (54 to 59 mg/dl) into the low-risk range (60 to 74 mg/dl). A two-way analysis of variance did not reveal any statistically significant difference among the three groups.

Of the many other variables relating to both lipids and heart disease, including diet, activity, family history, and smoking, the relationship to weight is illustrated in Fig. 3. Baseline values before hormone replacement are compared with values after hormone use according to the patient's weight. There were no differences in total cholesterol related to weight in the untreated women. Total cholesterol was 218.4 ± 6.45 mg/dl at baseline in those with normal weight, 217.4 ± 6.40 mg/dl in those weighing between 150 and 200 pounds, and 217.6 ± 6.59 mg/dl in those weighing >200 pounds. There was a moderate increase corresponding to increased weight in the hormone users: 202.8 ± 3.35 mg/dl with normal weight, 213.2 ± 4.16 mg/dl in those weighing between 150 and 200 pounds, and 231.3 ± 6.33 mg/dl in those weighing >200 pounds. Triglycerides increased markedly with increased weight both at baseline and with hormone use. At baseline, women weighing <150 pounds had mean triglyceride levels of 128.3 ± 7.80 mg/dl, compared with 147.6 ± 7.88 mg/dl in those weighing between 150 and 200 pounds and 234.4 ± 9.71 mg/dl in those weighing >200 pounds. In the hormone users triglycerides also increased markedly with increased weight: 132.7 ± 3.91 mg/dl in those with normal weight, 169.6 ± 6.45 mg/dl when weight was between 150 and 200 pounds, and 252.9 ± 9.44 mg/dl in those weighing >200 pounds. However, the only statistically significant difference was between the untreated women of normal weight (128.3 ± 7.80 mg/dl) and the hormone users weighing >200 pounds (252.9 ± 9.44 mg/dl), $p \leq 0.001$. HDL cholesterol decreased with increasing weight at baseline before hormone replacement from a mean of 64.9 ± 4.42 mg/dl with normal weight to 59.4 ± 4.13 mg/dl in those between 150 and 200 pounds and to 44.0 ± 3.16 mg/dl in those weighing >200 pounds. HDL cholesterol likewise decreased with increasing weight in the hormone users from 65.7 ± 2.50 mg/dl at normal weight to 59.9 ± 2.63 mg/dl between 150 and 200 pounds and to 54.3 ± 3.41 mg/dl in those weighing >200 pounds. There were similar changes as a result of increasing obesity with both LDL cholesterol and the total cholesterol/HDL ratio in that both increased with increasing weight at baseline and with hormone use.

The relationship of smoking and hormone use on lipid patterns are shown in Fig. 4. In every instance, except for HDL cholesterol, the hormone users, both nonsmoking and smoking, had lower mean values than the baseline before hormone replacement was begun.

Table III. Lipid profiles in women receiving estrogens, androgens, and carbon 19 progestogens

Hormone therapy	*No. of patients*	*Total cholesterol (mg/dl, mean ± SE)*	*Triglycerides (mg/dl, mean ± SE)*	*HDL cholesterol (mg/dl, mean ± SE)*	*LDL cholesterol (mg/dl, mean ± SE)*	*Total cholesterol/HDL ratio (mean ± SE)*	*LDL/HDL ratio (mean ± SE)*
50 mg Estradiol plus 75 mg testosterone	29	198.5 ± 5.69*	134.6 ± 8.87	65.9 ± 3.67	116.6 ± 5.12	3.24 ± 0.87	1.95 ± 0.76

High oral estrogen	0	—	—	—	—	—	—
Oral estrogen or testosterone	4	184.3 ± 5.62	102.3 ± 5.63	51.6 ± 1.97	124.3 ± 1.91	3.84 ± 0.85	2.59 ± 0.77
TOTAL	183	201.2 ± 5.73	140.9 ± 8.17	61.9 ± 3.84	120.0 ± 5.31	3.48 ± 0.96	2.12 ± 0.87

The mean HDL level in the smoking hormone users (56.3 ± 4.26 mg/dl) was between the mean HDL of nonsmoking untreated women (59.6 ± 4.04 mg/dl) and that of smoking untreated women (48.8 ± 3.69 mg/dl). The highest mean HDL cholesterol (63.5 ± 4.17 mg/dl) was observed in the nonsmoking hormone users. The only statistically significant differences in these groups were in HDL cholesterol values between the nonsmoking hormone users (63.5 ± 4.17 mg/dl) and the smoking hormone users (56.3 ± 4.26 mg/dl), $p \leq 0.001$, and between the nonsmoking hormone users and the smoking untreated women (48.8 ± 3.69 mg/dl), $p \leq 0.001$.

Four of these 556 postmenopausal women had evidence of coronary artery disease during hormone replacement therapy. Their clinical characteristics, years of hormone replacement at the time of cardiovascular event, and lipid values are given in Table IV. Although none has died of heart disease, two (patients 1 and 3) had cardiac catheterization because of angina and were treated with angioplasty and two (patients 2 and 4) underwent coronary bypass surgery after myocardial infarction. All were moderately obese but none were smokers. Although patient 1 had a total cholesterol level of 226 mg/dl, which was above the 200 mg/dl considered to be ideal, the rest of her lipid values were within the normal range. Triglycerides were elevated in three (patients 2, 3, and 4) and HDL cholesterol was quite low at 37 mg/dl in patient 3. Patient 4 had deteriorating lipid changes. At age 65, after 12 years of hormone replacement therapy, breast cancer was diagnosed; therefore the estrogen was discontinued and two pellets of testosterone (150 mg) were implanted every 6 months, along with C-19 progestogen given orally for 13 days every month. At diagnosis of the breast cancer her lipid pattern was elevated, except for HDL cholesterol. During the next 3 years, without the estrogen therapy, total cholesterol, triglycerides, LDL cholesterol, and total cholesterol/HDL ratio all increased while HDL decreased to 39 mg/dl in spite of a cholesterol-control diet. At age 68, after 3 years without estrogen replacement, a myocardial infarction occurred and she was treated with coronary bypass surgery. At 2 years after the myocardial infarction, she has lost some weight, is more carefully controlling cholesterol intake, and has continued to receive the androgen-progestogen replacement without estrogen. Lipid patterns are better but still compromised.

Comment

It is clear that there is a protective effect from cardiovascular disease with estrogen replacement therapy. How this is mediated is still to be firmly established. There is a role through lipids in that estrogens decrease total cholesterol, primarily through a decrease in LDL cholesterol. The total cholesterol/HDL cholesterol ratio is improved since estrogens also may increase HDL cholesterol. This may vary by type and dosage of es-

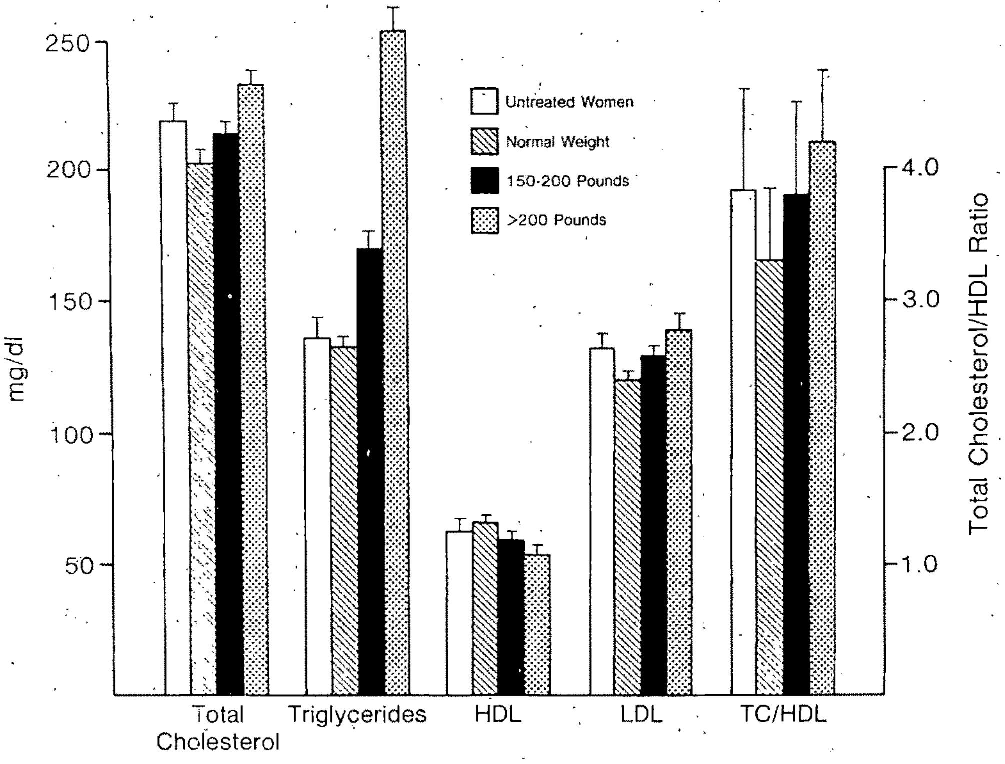

Fig. 3. Mean values of various lipids at baseline before hormone replacement *(Untreated women)* compared with values in hormone users according to weight. All values are expressed as mean ± SE.

trogen, route of administration, and particularly the duration of therapy. Nonoral routes of administration of estrogen replacement, such as the subcutaneous estradiol pellets used in this study, have been shown to significantly increase HDL cholesterol.[14] In a comparison of estradiol administered by subcutaneous pellet or transdermal patch, HDL cholesterol increased significantly by 12 weeks with the pellet but 24 weeks was required to show a significant increase with the patch. The total cholesterol/HDL ratio also was significantly decreased at 12 weeks with the estradiol pellet whereas 24 weeks was necessary to show a significant decrease with the estradiol patch.

A few studies have shown that there may be an adverse effect of progestogens, particularly on HDL cholesterol, and primarily by the 19-nortestosterone progestogens.[10, 15] However, most of these are short-term studies, usually of 3 months' duration. What is really important are the long-term effects of hormone replacement because the benefits of hormone replacement, such as prevention of osteoporosis and cardiovascular disease, require long-term use. Our data would indicate that there are really no adverse effects of added progestogens over the long term since the majority of the various lipids and lipoproteins remain within the normal range. Even when androgens in the form of testosterone pellets are included in hormone replacement, there was little difference in mean HDL cholesterol values: 67.0 ± 3.94 mg/dl in the unopposed estrogen-androgen users, 64.5 ± 4.16 mg/dl in the estrogen–androgen–C-21 progestogen users, and 61.9 ± 3.84 mg/dl in the estrogen–androgen–C-19 progestogen users. The total cholesterol/HDL ratios were likewise very favorable, 3.55 ± 0.83, 3.50 ± 1.01, and 3.48 ± 0.96, respectively, all well below the 4.44 average-risk ratio. Other long-term studies indicate a significantly improved LDL/HDL ratio with estrogens combined with C-19 progestogens[16, 17] or estrogens combined with C-21 progestogens.[18]

It may be the dosage of estrogen that is most important in improving the lipid pattern to decrease the risk for cardiovascular disease. In a study comparing different dosages of micronized estradiol, 1, 2, and 4 mg, combined with a standard dosage of a C-19 progestogen, norethindrone acetate 1 mg for 11 days, HDL cholesterol increased significantly only with 2 and 4 mg of estradiol.[19] Total cholesterol decreased significantly only with 4 mg estradiol combined with 1 mg norethindrone acetate, but there were significant decreases in LDL cholesterol with all three dosages of estradiol. In studies from the Lipid Research Clinics there was also a dosage response between 0.625 and 1.25 mg conjugated estrogens.[12] Total cholesterol increased slightly with 0.625 mg while it decreased with 1.25 mg. HDL

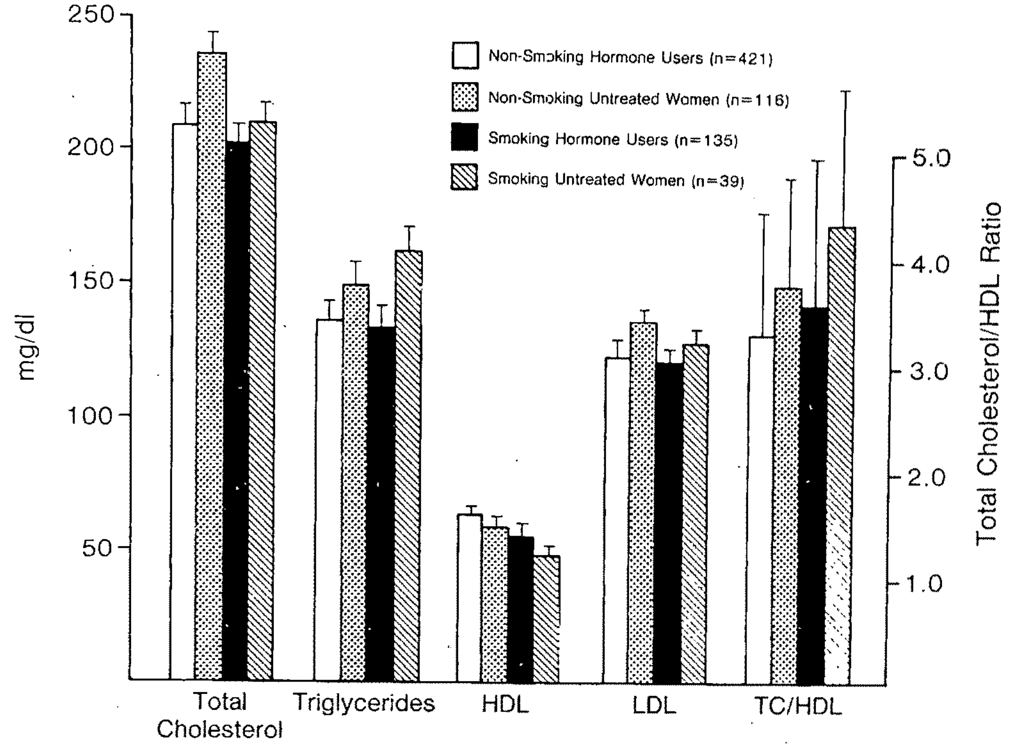

Fig. 4. Mean values of various lipids at baseline before hormone replacement *(Untreated women)* compared with values in hormone users according to smoking status. All values are expressed as mean ± SE. Numbers in each group are shown in parentheses.

Table IV. Patients with coronary artery disease

Patient No.	Age (yr)	Weight (lb)	Duration of hormone therapy (yr)	Total cholesterol (mg/dl)	Triglycerides (mg/dl)	HDL cholesterol (mg/dl)	LDL cholesterol (mg/dl)	Total cholesterol/HDL ratio
1	69	189	8	226	97	74	127	3.03
2	66	174	15	223	555	62	145	3.58
3	54	165	12	226	303	37	120	6.11
4	65	189	—	254	228	56	157	4.54
—	—	189	—	256	269	46	169	5.54
—	—	188	—	241	260	49	144	4.94
—	—	194	—	275	245	47	204	5.85
—	68	191	15	269	264	39	203	6.83

cholesterol increased and LDL decreased with both dosages of conjugated estrogens, but the change was greater with 1.25 mg. Our data, as well as these other long-term studies, indicate that progestogens, even androgenic progestogens, do not negate the estrogen-induced increase in HDL cholesterol and decrease in LDL cholesterol over the long term, especially when adequate dosages of estrogens are given.

Factors that seem to affect lipids and lipoproteins more than progestogens in estrogen users are obesity and smoking. Increasing weight gave higher mean values of total cholesterol and LDL cholesterol, and particularly triglycerides while decreasing the levels of HDL cholesterol. Smoking not only depressed HDL cholesterol but also increased total cholesterol, triglycerides, and LDL cholesterol in untreated women. According to our data in the 155 women who had baseline values measured before hormone replacement for up to 30 years after menopause, total cholesterol tends to rise within the first few years of estrogen deficiency, primarily because of an increase in LDL cholesterol. Triglycerides also increase with estrogen deprivation but were very variable, more related to obesity. HDL cholesterol did not change after menopause, even with >25 years of estrogen deficiency. A recent study from Denmark also observed significant increases in total cholesterol, LDL cholesterol, and triglycerides after menopause.[20] They also observed a significant decrease in HDL cholesterol but the decline occurred gradually over the 2 years preceding the cessation of menses with no further decrease after menopause.

That the tremendous cardioprotective effect of estrogen replacement is not totally mediated through lipids seems to be indicated by the individual lipid patterns in four of our 556 postmenopausal women with coronary artery disease. All were obese but none were smokers. The lipid pattern was entirely normal in one, triglycerides were elevated in three, but only one had a depressed HDL cholesterol level. One patient who had a deteriorating lipid pattern during the 3 years after estrogen therapy was discontinued from the study because of breast cancer, which probably played a major role in the subsequent myocardial infarction. However, other factors may be important, such as a direct effect of estrogen on arterial walls because estrogen receptors have been identified. Estrogens may improve vascular blood flow, even dilate coronary arteries, decrease platelet adhesiveness, and also be mediated through prostacyclin and thromboxane metabolism.[21, 22]

Discussion

DR. WALLACE C. NUNLEY, JR., Charlotte, North Carolina. Cardiovascular disease is the leading cause of morbidity and death among postmenopausal women in the United States. Previous epidemiologic studies have determined that the incidence of cardiovascular disease for women begins to increase before and "accelerates" after menopause. The loss of natural estrogen production at the time of menopause seems to have an adverse effect on the female cardiovascular system.

Attention has been directed to an individual's lipid profile as a predictor for cardiovascular disease. The higher the total cholesterol, the higher the LDL, and the lower the HDL levels herald an increased risk of disease. With the onset of menopause, there are significant increases in the levels of total cholesterol and LDL, as well as triglycerides, compared with the premenopausal state. The level of HDL cholesterol begins to decline gradually, approximately 2 years before menopause.[1] These alterations occur without changes in the individual's weight and are thereby attributed mainly to the loss of estrogen production. Thus the stage is set for the hypothesis that estrogen replacement may alter one's lipid levels to a more favorable profile and decrease cardiovascular disease risk in the menopausal woman, a practice of true preventive medicine. Bush et al.,[2] in the Lipid Research Clinics Program, published data in 1987 that concluded that, after a mean of 8.5 years of estrogen replacement therapy, women not only had a lower incidence of cardiovascular deaths than non–estrogen users had but also had a significantly lower risk of death from all causes. The beneficial lipid effects of estrogen replacement therapy are dependent on dosage, duration of treatment, and delivery system.

Because of consistently documented increases in the risk of adenocarcinoma of the endometrium with estrogen replacement therapy, the addition of a progestin was proposed. Combination hormone replacement therapy eliminated the endometrial adenocarcinoma risk.[3] However, progestin usage created another health concern, namely, potential adverse effect on lipid profile.

Before the current report of Drs. Gambrell and Teran, information was available that estrogen-progestin therapy, in various dosages and with different compounds, could be used without significantly adversely affecting the beneficial lipid alterations achieved with estrogen replacement alone. In the majority of reports, however, treatment was limited to a few weeks up to a maximum of 2 years.

The study presented today attempts to reassure clinicians who advocate this treatment in the postmenopausal woman. After a mean of 12 years of therapy, three groups of women (those treated with estrogens alone, estrogens plus C-21 progestins, and estrogens plus C-19 progestins) continued to have reassuring lipid ratio profiles. In addition, correlation of these lipid levels and ratios was applied to the incidence of cardiovascular disease. Only 4 of the 556 women had evidence of coronary artery disease during hormone replacement therapy, and all 4 were defined as obese, another risk factor. Although it is unclear as to which of the three groups these women belonged, the small absolute number affected tends to reassure clinicians that combined hormone replacement therapy in the doses described is not associated with increased risk of cardiovascular disease. Furthermore, as stated by the authors, the cardioprotective effect of estrogen replacement is not totally mediated through lipids.

Smoking increases one's risk of cardiovascular disease. In this presentation the HDL cholesterol level statistically was greater in the nonsmoking hormone users than in the smoking hormone users and the smoking untreated women. Smoking may accelerate estrogen metabolism, and thus smokers have lower endogenous estrogen levels than do nonsmokers. This may account for the changes depicted in the HDL cholesterol level. Quantity of cigarettes smoked and/or number of pack years were not defined in this study.

A total of 103 of the 132 (78%) unopposed estrogen users and 363 of the 424 (85.6%) estrogen-progestin users received concomitant androgen therapy. What effect, if any, did the addition of testosterone have on the lipid profile, because androgens can decrease HDL and increase LDL concentrations in certain clinical situations? Sherwin et al.[4] reported in an earlier study that the addition of 150 mg testosterone intramuscularly monthly did not yield different lipid levels compared with those of women receiving estrogen alone. Similarly, in this study the addition of androgens did not seem to affect adversely the individuals depicted.

According to Stanczyk et al.,[5] the use of a 25 mg estradiol pellet yields a peripheral estradiol level of 40 to 70 pg/ml over a 6-month period and two 25 mg pellets yield a level of 95 to 126 pg/ml over the same period of time. Higher estrogen levels should yield improved lipid levels and lipid ratio profiles. The study by Gambrell and Teran is consistent with this because their results yield a trend of improved lipid profiles with an increase in the number of estrogen pellets used.

Although not a randomized prospective study, this cross-sectional study has sufficient numbers of women at extended periods of time from menopause and treatment to add reassurance regarding risk of cardiovascular disease to clinicians and patients who use combined hormone replacement therapy.

I have the following questions for Dr. Gambrell:

1. With the knowledge gained from this study regarding the impact of long-term estrogen-progestin therapy on an individual's lipoprotein cholesterol profile, what is his current recommendation regarding combination therapy in a woman who has undergone hysterectomy?
2. In addition to the information gained today regarding long-term estrogen and/or androgen-progestin therapy on lipid profiles and incidence of cardiovascular disease, does Dr. Gambrell have any additional information regarding number of women experiencing wrist, hip, or spine fractures, or strokes, or breast cancer from this same cohort?
3. Did any women have peripheral estrogen levels measured in this cross-sectional study? Were any androgen levels measured to see if the addition of this hormone had any effect on the circulating estrogen level?

Dr. Gambrell (Closing). For 6 years we have recommended that all women on a regimen of estrogen replacement, whether they do or do not have an intact uterus, be given a progestogen. Many physicians were doing this several years ago, and then the lipid issue arose and some backed off. There are two benefits from the added progestogen other than the prevention of endometrial cancer. There is added protection of the bones in that adding progestogen to estrogen replacement over a 10- to 12-year period can increase bone density. That is the only form of therapy known to do it. Our data, now confirmed by two others, show that the addition of a progestogen decreases the incidence of breast cancer for some women. This is controversial, as you well know, but there are more data coming out of New York later this year that will confirm this finding.

Do we have any fractures in our patients? We had no wrist or hip fractures. We don't know of any spine fractures, but there may be silent lumbar compression fractures. Unless roentgenography is being done for back pain, you may not pick these up. There were no strokes. Breast cancer developed in one patient after 12 years. We have had eight other patients on regimens of testosterone and progestogen only because they had breast cancer.

What about estrogen and androgen levels? With two pellets of 50 mg estradiol over the long term blood levels will be approximately 200 pg of estradiol. With two testosterone pellets the total testosterone level will range between 110 and 190 ng, which is higher than in most women. Free testosterone is usually 3 to 7 ng, which is the upper limit of normal for most women. When you are giving estrogen, bound testosterone levels are higher, so there aren't as many side effects from the androgens as you might expect.

Endometrial morphology in asymptomatic postmenopausal women

Few data are available regarding endometrial histologic features in asymptomatic perimenopausal and postmenopausal women. This study encompasses endometrial biopsy specimens obtained from 801 such women before enrollment in a multicenter study of estrogen-progestin replacement. One endometrial cancer was found (0.13%); four additional biopsy specimens showed atypia (total 0.63%). The endometrium was atrophic in 373 (46.9%), proliferative in 133 (16.7%), secretory in 54 (6.8%), and hyperplastic in 41 (5.2%). Insufficient tissue for diagnosis was obtained in 195 (24.5%). We conclude that the yield for neoplasia is so low that screening endometrial biopsy is not justified in asymptomatic perimenopausal and postmenopausal women. (AM J OBSTET GYNECOL 1991;165:317-22.)

Key words: Histology, endometrial; menopause; carcinoma; endometrium; hyperplasia

Endometrial cancer occurs at an incidence rate of 0.72 per 1000 women.[1] In 1986 it was estimated that there were 36,000 new cases of endometrial cancer in the United States, compared with 14,000 cases of cervical cancer.[2]

Endometrial biopsy has been associated with a high degree of sensitivity and specificity for the detection of endometrial cancer in a patient population with symptoms.[3-5] The value of screening a postmenopausal population without symptoms is debatable. Recently, the Canadian Task Force on the Periodic Health Examination concluded that screening for endometrial cancer be excluded in postmenopausal women without symptoms.[6] They base their reasoning on the following facts. Endometrial cancer manifests early with vaginal bleeding and has a high 5-year survival rate (75%). No con-

trol trials have been conducted to evaluate the effectiveness of prevention or treatment in changing the outcome of endometrial cancer. Last, screening of high-risk women would detect only 50% of cases of endometrial cancer.

Several reported techniques can be used for obtaining both cytologic and histologic material from the uterine endometrial cavity in outpatients.[7,8] On the basis of results from a large screening of women without symptoms ($N = 2586$) aged >45, Koss et al.[9] have recommended routine screening of women for endometrial carcinoma because they found an incidence of 6.96 cancers per 1000 women by use of an endometrial cytologic technique. This report is derived from a multicenter clinical trial of estrogen and progestin replacement therapy in perimenopausal and postmenopausal women. We have evaluated the endometrial biopsy results from 801 asymptomatic perimenopausal or postmenopausal women to determine prospectively the incidence and/or prevalence of abnormal endometrial histologic characteristics.

Material and methods

Volunteers. The women recruited for this study were all volunteers who were interested in hormonal replacement for relief of menopausal symptoms. The protocol and informed consent had been approved by the local institutional review boards at each clinical site. Each volunteer was apprised of the reason for the study and had signed an informed consent form before any investigative procedure. Because of the nature of the study, all volunteers were required to have an intact uterus and no evidence of estrogen-dependent neoplasia of either the breast or the reproductive tract. Volunteers also were excluded if there was evidence of drug or alcohol abuse, thrombophlebitis, or thromboembolic disorders. Serum follicle-stimulating hormone levels were obtained on all women who were <45 years old or who had equivocal clinical symptoms. A serum follicle-stimulating hormone level >100 mIU/ml and a luteinizing hormone level >75 mIU/ml were indicative of the postmenopausal state. All volunteers who had received exogenous sex hormones were required to have discontinued all hormonal medication for at least 60 days before enrollment (biopsy) in the study.

Endometrial biopsy. Each volunteer underwent a screening endometrial biopsy with the sample being obtained from the anterior and posterior uterine walls. The endometrial samples were immediately placed in 4% paraformaldehyde in phosphate buffer containing 0.25% cetylpyridinium chloride. All samples were then shipped to the Electron Microscopy Center of the Department of Anatomy at the College of Medicine, University of South Alabama, for histologic evaluation by two of the authors (W.W.W. and E.A.D.) using light microscopy. Each biopsy specimen was then categorized by the same two authors using the following criteria:

1. Atrophy. This broad category includes the patterns of marked atrophy, inactive endometrium of perimenopausal type, posthyperplastic atrophy, and progestin-suppressed endometrium. Some epithelial snouts and vacuoles may be present.
2. Proliferative endometrium. The endometrium shows discernible evidence of stimulation—small,

tubular glands, fine cytoplasmic vacuoles, and columnar surface epithelium, with ciliation and mitoses in epithelial cells and/or stroma.

3. Secretory endometrium. Glands may show subnuclear glycogen vacuoles with more advanced secretory change; glands are tortuous with luminal secretion. Stroma is hypertrophic with periarteriolar cuffing. Mitoses are rare or absent.
4. Hyperplastic endometrium. A spectrum of glandular patterns (cystic, outpouching, or complex), crowding (glands at the expense of stroma), and cytologic abnormality characterizes the diagnostic subcategories of cystic, adenomatous, and atypical hyperplasia.
5. Insufficient for definitive diagnosis.

Results

For the purposes of this analysis we used the pathologic diagnosis of each sample by one author (E.A.D.). Screening endometrial biopsies were performed in 801 women. Seven hundred thirty-two were enrolled in the hormone replacement study as of the cutoff date, Dec. 31, 1988. The enrolled women were 52.1 ± 5.7 years old (mean ± SD, range 37 to 75) and weighed 148.4 ± 29.1 pounds (mean ± SD, range 87 to 274) (Table I). Postmenopausal status, defined as at least 12 months since a menstrual period, was assigned to 49.2%; perimenopausal status (<12 months since a menstrual period), to 48.9%, and unrecorded menopausal status, to 1.9%. The group comprised 90.4% white women, 4.4% black women, 4.5% Hispanic women, and 0.7% women of other ethnic groups.

Results of the 801 screening biopsies are shown in Table II and in Fig. 1. Histologic evidence of atrophy was noted in 373 (46.9%). Proliferative endometrium was found in 133 (16.7%), while secretory changes were shown in 54 (6.8%). It was not possible to relate biopsy results to previous use of sex hormones.

Hyperplastic endometrium was found in 41 (5.2%), and an additional 5 women had atypical cellular changes necessitating a repeat biopsy. The two hyperplasia groups were further classified into simple (31, 3.9%), cystic (9, 1.13%), and adenomatous (1, 0.13%). The five atypical cellular findings that necessitated further evaluation resulted in diagnosis of one case of well-differentiated adenoacanthoma.

Screening biopsy specimens contained insufficient tissue for a diagnosis in 195 (24.50%). These specimens contained endocervical tissue or mucus only, or fragments of endometrium too minute to evaluate, or no discernible tissue at all.

Polyps were found in 9 samples (1.13%). All these specimens except one also contained sufficient additional endometrium for another diagnosis, including atrophy, proliferative endometrium and cystic hyperplasia. These biopsy specimens have been classified according to these diagnoses. Other miscellaneous findings included acute endometritis (2 patients).

Table I. Demographic characteristics of women enrolled in this study

Total	732
Age (yr)	
Mean ± SD	52.1 ± 5.7
Range	37-75
Weight (lb)	
Mean ± SD	148.4 ± 29.1
Range	87-274

All	41	5.2
Simple	31	3.9
Cystic	9	1.1
Adenomatous	1	0.1
Cellular atypia	5	0.6
Insufficient tissue	195	24.5

Comment

It is axiomatic in gynecology that appropriate diagnostic studies should be performed in women with abnormal uterine bleeding. This is particularly relevant in postmenopausal women; any bleeding should arouse suspicion of neoplasia.

This study addresses the issue of endometrial biopsy in asymptomatic perimenopausal and postmenopausal women before initiation of hormone replacement therapy. No large-scale histologic study addressing this issue has been published.

Endometrial carcinoma was found in 1 of 801 asymptomatic women for an incidence of 1.3 per 1000. The expected incidence of endometrial carcinoma is approximately 1 to 2 per 1000 woman years.[9]

Our yield is lower than that of Koss et al.,[9] who discovered 16 cases of endometrial carcinoma in 2586 women on first screening, for a rate of 6.2 per 1000. However, 21.8% of this group were estrogen users.

Furthermore, this group was solicited for the purpose of cancer screening; thus self-selection bias may have increased the risk of this population. In fact, Koss et al. believed that some patients concealed symptoms of abnormal bleeding. In contrast, our study group was solicited for entry into a hormone replacement study, and the women were required not to have any abnormal bleeding. Thus our population may not be comparable with that in Koss's study.

Approximately three fourths of the women in our study had either atrophic endometrium or insufficient tissue on biopsy. Most of these insufficient specimens were thought to result from endometrium so atrophic that an adequate sample could not be obtained. It is therefore unlikely that significant endometrial pathologic abnormality was missed.

Proliferative endometrium was found in 16.7% of our population, and secretory changes were shown in 6.8%. We were not able to determine whether these results reflect endogenous or exogenous hormone action. However, all volunteers were free of hormonal medication for a minimum of 60 days before biopsy. Because 49% of the women were perimenopausal, it would not be unexpected to find evidence of endogenous stimulation of the endometrium.

We conclude from this study that the incidence of endometrial carcinoma in perimenopausal and postmenopausal women without symptoms is low; therefore, routine biopsy in such a group is a low-yield procedure. Some would conclude that biopsy before hormone therapy is indicated in spite of the low rate of positivity, a view espoused by two of the authors (W.W.W. and E.A.D.). Others, including two other authors (D.F.A. and K.M.S.), would conclude that biopsy in women without symptoms is unwarranted, in view of the low rate of abnormality in this group and the early onset of bleeding in women with endometrial neoplasia. This latter approach has also been recommended by the Canadian Task Force.[6] We all agree that women with symptoms require appropriate investigation. It should be reemphasized that conclusions that are based on our data apply only to women without symptoms. We do believe that all women receiving unopposed estrogens need yearly endometrial sampling. This should be a very small group of women, on the basis of current recommendations to use combined estrogen-progestin replacement.

Discussion

DR. CECIL F. LANGFORD, Spartanburg, South Carolina (Official Guest). Dr. Archer and his colleagues are to be commended in accepting the challenge of a formidable and time-consuming study. The meticulous design of their research endeavor, the clarity of criteria for patient selection, the precise definitions of the histopathologic interpretations, and the analysis and collation of the findings provide us with valid criteria for understanding and clinical application of the results.

Certain observations seem worthy of comment. The fact that 46.8% of the biopsies produced atrophic endometrium and 24.5% of them produced insufficient tissue for diagnosis meant that 71.3% of the specimens could not be interpreted because of total absence or inadequacy of tissue obtained at biopsy. This will initially institute some concern over the accuracy of the study. Whereas the article states that both the anterior and posterior walls of the endometrium were sampled, it is not clear what type of instrumentation was used in obtaining the tissue. This is of some importance because most gynecologists and indeed pathology laboratories have their own preference as to the instruments found to be more efficacious in their hands for adequate sampling (i.e., Vabra aspiration, Gravely jet wash, Novak aspiration curette, Pipelle aspiration cannula). The authors did not indicate which technique was used in this study.

The observation that adenocarcinoma of the corpus uteri may in some instances be focal in its origin and its distribution might again raise the question of adequate sampling. In spite of this, current opinion suggests that endometrial sampling by most modern techniques, in contrast to results of older studies, results in a higher degree of accuracy and adequate assessment of the endometrial surface epithelium.

Without question, the most reassuring result of the study in 796 women is that only one case of overt adenocarcinoma was found. Four other biopsy specimens demonstrating cellular atypia required further evaluation. We believe that hyperplasia without atypia is not a premalignant lesion; therefore these four cases of atypia must be viewed with concern because 20% of cases with atypical adenomatous hyperplasia are associated with an occult or unrecognized well-differentiated adenocarcinoma of the endometrium.

Endometrial cancer manifests early with vaginal bleeding and has a 5-year survival rate of 75%; one wonders if the results would be improved by routine screening. Williamson (personal communication, 1990) found only three cases of atypical epithelia in 100 high-risk patients (overweight diabetic patients considered to be at high risk).

Continuous unopposed estrogen therapy is believed by many to be associated with if not the causative factor in certain cases of adenocarcinoma of the uterine corpus. Current trends that include the use of a combination preparation including estrogens and a progestogen not only are more logical from a physiologic standpoint but also will reduce the population considered at risk because they do not periodically receive a progestational agent to induce periodic shedding of the endometrium. This is alluded to by Dr. Archer in that in the future there will be a decreasing patient population requiring periodic endometrial sampling.

Numerous publications in the lay and medical press provide convincing evidence of the value of postmenopausal hormonal therapy. These include its impact on the reproductive tract, skin and its appendages, and urinary tract epithelium, the maintenance of urinary continence, and, paramount to all of the above, prevention or amelioration of the crippling effects of osteoporosis. In the same publication the patient and the gynecologists are warned that such therapy may be carcinogenic. Studies such as this one should minimize or at least put into perspective many of these concerns. Added to the acceptance by the patient will be the absence of vaginal bleeding; we find such bleeding to be a major negative factor in patients' attitudes toward postmenopausal therapy.

I agree that the yield of neoplasia in this study is so low that screening endometrial biopsy is not justified in perimenopausal and postmenopausal women without symptoms.

In conclusion, the authors have comprehensively assessed the endometrium in a large group of perimenopausal and postmenopausal women. I would pose only one question: Do you have a follow-up plan designed to assess the subsequent evaluation of endometrial changes, particularly preneoplastic or neoplastic lesions in the patient population?

DR. WALLACE C. NUNLEY, JR., Charlotte, North Carolina. Dr. Archer, five patients had endometrial histologic abnormalities, and presumably these patients might respond to a progestin challenge. Would you consider, instead of a routine endometrial biopsy, a progestin challenge? If that were positive, it would select a group of patients in whom biopsy might be indicated, in contrast to the 75% of patients with inadequate tissue or atrophic endometrium, in whom you probably would not get a positive progestin response.

DR. JAROSLAV F. HULKA, Chapel Hill, North Carolina. Vaginal ultrasonography has recently been documented to be a fairly good screen for endometrial changes. Would you care to comment or speculate on the future role of the combination of biopsy and vaginal ultrasonography?

DR. R. DON GAMBRELL, JR., Augusta, Georgia. I would like to point out a study of a much smaller number of patients reported in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in 1984 by Hanna et al., in which they gave a challenge of 100 mg progesterone in only 30 patients. Seventeen percent had withdrawal bleeding. They performed biopsies in all these women. The ones who did not have withdrawal bleeding had atrophic, inactive endometrium, and in 60% of the ones who had withdrawal bleeding there was some degree of endometrial hyperplasia.

DR. ARCHER (Closing). Dr. Langford pointed out the issues confronting us in terms of sensitivity and the concerns we had about sampling techniques. We have follow-up plans. As I have mentioned, 796 women were screened and 732 were enrolled in this study. Dr. McIntyre-Seltman and I are currently reevaluating these data because they were put into six different treatment arms with estrogen-progestin replacement therapy. Endometrial biopsies were carried out after 6 and 12 months of treatment at the appropriate times in the cycles. We are evaluating those data at the present time.

One of our concerns is whether we should be doing progesterone challenge tests. At the present time we are uncertain as to its efficacy. I feel that if I am going to place a woman on a hormone replacement therapy regimen, I will go ahead and do so, arguing that I am going to use both an estrogen and a progestin and thereby circumvent significant endometrial changes. I have used the progesterone challenge test in the past. Dr. Gambrell has published on this very issue in terms of the use of progestins in early perimenopausal and postmenopausal women.[1] I admit that it will sort out those women who have atrophic endometrium from those who have some degree of stimulation. I don't have any data to support the fact that a significant group of women with bleeding may be more at risk for endometrial adenocarcinoma or hyperplasia.

We have been doing vaginal ultrasonographic examinations on patients who are on hormone replacement therapy regimens as a part of clinical studies under various protocols. I am well aware of the data from Europe, in postmenopausal women who have experienced vaginal bleeding, that an endometrial thickness >5 mm by ultrasonography will identify a group of women likely to have some abnormality of the endometrium.[2] On the other hand, when the endometrial thickness is <5 mm, one would expect to find an atrophic endometrium. We have not done enough studies in patients to find a correlation. We are doing ultrasonographic examination before endometrial biopsy in several clinical protocols in women who are receiving estrogen and progestins.

How good is ultrasonography in assessing the entire endometrial cavity? I am a neophyte in this area, and I feel very inadequate, thinking that I might miss something, if I look at a vaginal sonogram that I have obtained in terms of endometrial thickness. This goes back to the same point that adenocarcinoma can be focal, and we may be missing something with these biopsies. The use of vaginal ultrasonography is interesting in the evaluation of the endometrium, but I am not sure of its clinical validity.

Assessment of Kegel pelvic muscle exercise performance after brief verbal instruction

Richard C. Bump, MD, W. Glenn Hurt, MD, J. Andrew Fantl, MD, and Jean F. Wyman, PhD
Richmond, Virginia

Forty-seven women had urethral pressure profile determinations performed at rest and during a Kegel pelvic muscle contraction, after brief standardized verbal instruction. Twenty-three (49%) had an ideal Kegel effort—a significant increase in the force of urethral closure without an appreciable Valsalva effort. Twelve subjects (25%) displayed a Kegel technique that could potentially promote incontinence. Age, parity, weight, estrogen deprivation, prior continence surgery or hysterectomy, and passive urethral function did not predict a successful effort. We concluded that simple verbal or written instruction does not represent adequate preparation for a patient who is about to start a Kegel exercise program. (Am J Obstet Gynecol 1991;165:322-9.)

Key words: Kegel exercises, pelvic muscle exercises, urinary incontinence

In the late 1940s, the gynecologist Arnold Kegel[1] proposed the use of pelvic muscle exercises to improve the function and tone of the pelvic floor after childbirth, to correct mild anatomic defects such as early cystocele and rectocele, and to treat stress urinary incontinence. Kegel exercises represent the voluntary contraction and relaxation of the levator ani muscle (principally the pubococcygeus and puborectalis portions), which supports the vagina, bladder, and urethra and which contributes to the skeletal muscle component of the urethral sphincteric mechanism. The goal of Kegel exercises in the treatment of urinary incontinence is to increase the strength and endurance of these muscles, thereby enhancing the force of urethral closure under certain conditions, such as with a sudden increase in abdominal pressure. Implicit to our understanding of the physiologic basis of Kegel exercises is that a properly performed contraction should increase the force of urethral closure.

Some women seem unable to contract the proper muscles when given verbal instruction about Kegel exercises; they often perform a Valsalva maneuver or contract the gluteal and thigh muscles exclusively or in combination with contraction of the levators. Kegel noted that many women are unaware of their pelvic

muscle function and require some method of performance feedback to successfully contract the proper muscles. To assist patients by providing such biofeedback, he developed the perineometer, a pneumatic device consisting of a vaginal probe connected to a manometer. While vaginal pressure measurements, electromyographic activity, and digital palpation of pubococcygeus muscle tone have all been advocated as biofeedback techniques to facilitate the initiation of a Kegel exercise program, most patients start (and finish) such a program with only brief written or oral instructions. The American College of Obstetricians and Gynecologists' patient education pamphlet on urinary incontinence instructs patients to "stop the flow of urine in midstream without tightening or tensing your leg or stomach muscles." The aim of this study was to assess the effect of such a simple brief verbal instruction on urethral sphincteric function during a Kegel contraction. A secondary aim was to attempt to identify clinical or urodynamic characteristics that might predict an effective Kegel contraction effort.

Subjects and methods

The study population included 47 consecutive subjects who presented to the Gynecologic Urodynamic Laboratory at the Medical College of Virginia Hospitals for evaluation. Their mean age was 53.6 years (range 23 to 83 years) and their mean parity was 2.5 (range 0 to 8). Twenty-eight subjects (60%) had urinary incontinence as the major complaint. Of those who were incontinent, 14 had pure genuine stress incontinence, four had pure detrusor instability, six had mixed incontinence (genuine stress incontinence plus detrusor instability), and four had pure urethral instability. Nineteen subjects (40%) did not complain of incontinence. Five of these had vaginal vault prolapse, four had emptying phase defects, five had sensory urgency without incontinence or motor instability, and five were being evaluated 6 months after successful continence surgery. Eighteen subjects (38%) had prior continence surgery, 27 (60%) had a prior hysterectomy, 7 (15%) had severe pelvic organ prolapse (2 of whom also had detrusor instability), and 7 (15%) were hypoestrogenic.

All subjects underwent a standardized urodynamic evaluation that included uroflowmetry with postvoid residual urine volume measurement, retrograde provocative multichannel water urethrocystometry with the use of microtip transducer catheters, passive and dynamic urethral pressure profiles, resting and stressed urethral axis determinations, and direct visualization testing for fluid loss. Specific details of the urodynamic methods have been described in detail previously.[2-4] All subjects had a negative bacterial urine culture (<100 CFU/ml) before being scheduled for urodynamic testing and none had pyuria at the time of the testing.

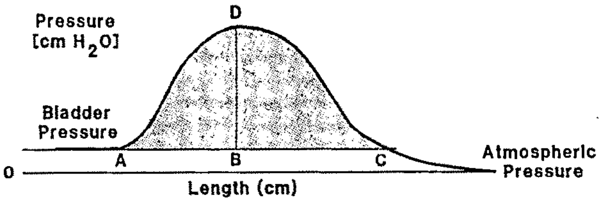

Fig. 1. Measurements derived from the urethral pressure profile. *Line A to C* is total functional urethral length; *line B to D* is maximum urethral closure pressure. *Shaded area* represents total urethral pressure profile area. Mean urethral closure pressure is calculated by dividing profile area by functional urethral length.

After each subject had completed the standard passive and dynamic urethral pressure profile (at a bladder volume of 300 ml and a transducer withdrawal speed of 0.5 mm/sec), a passive urethral pressure profile was repeated at a catheter speed of 5.0 mm/sec. Each subject was then asked to "contract the muscles you would use if you were trying to keep from losing your urine or if you were trying to stop your stream after you had started to urinate." Once the subject had acknowledged that she understood the instructions and had practiced a contraction, she was allowed to relax for a short time. It was then explained that she would be asked to contract the same muscles on command and to hold the contraction until she was told she could relax. Another urethral pressure profile was then performed, with the patient having been asked to start a contraction just before catheter withdrawal was started and being allowed to relax as soon as the urethral closure pressure became negative. This profile was designated the Kegel urethral pressure profile. The catheter withdrawal speed of 5.0 mm/sec allowed all Kegel profiles to be completed in <8 seconds, a period of time for which most patients could sustain a single contraction effort.

Pressures recorded with a physiologic recorder during the profiles included the vesical, urethral, abdominal (vaginal), detrusor, and urethral closure pressures. Parameters measured and analyzed from the urethral pressure profiles included the functional urethral length, maximum urethral closure pressure, total profile area (determined with a polar compensation planimeter), and mean urethral closure pressure (profile area/functional urethral length). These measurements are illustrated in Fig. 1. Urodynamic techniques and measurements, terms, and diagnostic criteria conform to the recommendations of the International Continence Society.[5]

A subject was considered to have had an effective Kegel effort if the Kegel urethral pressure profile area was ≥120% of the passive urethral pressure profile area or if both the Kegel maximum urethral closure pressure and the mean urethral closure pressure were

*Kruskal-Wallis one-way analysis by ranks.

≥120% of the passive maximum and mean urethral closure pressure. Subjects who did not fulfill either of these criteria were considered to have had an ineffective Kegel effort. The degree of Valsalva effort was assessed by measuring the changes in vesical and vaginal pressures. The Valsalva effort was considered excessive if the rise in vesical pressure exceeded 15 cm H_2O during the Kegel urethral pressure profile.

Categoric data were analyzed for significant differences with the χ^2 test with Yates' correction. Quantitative data were analyzed with analysis of variance and the Kruskal-Wallis one-way analysis by ranks for between-group comparisons, the paired *t* test for passive and Kegel urethral pressure profile comparisons, and simple linear regression analysis for vesical and vaginal pressure correlations.

Results

Twenty-eight subjects (60%) had an effective Kegel effort and 19 (40%) had an ineffective effort. With a Kegel contraction the former group increased the maximum urethral closure pressure (mean ± SE) from 35.0 ± 3.2 to 51.5 ± 3.7 cm H_2O ($p = 0.000001$), the total profile area from 449 ± 54 to 671 ± 68 mm × cm ($p = 0.0000008$), and the mean urethral closure pressure from 18.7 ± 2.0 to 28.1 ± 2.4 cm H_2O ($p = 0.0000004$). In contrast, the group with an ineffective effort had no significant increases in any of these parameters with maximum urethral closure pressure values of 32.2 ± 3.5 and 30.7 ± 3.6, total profile areas of 440 ± 53 and 386 ± 58, and mean urethral closure pressure values of 17.4 ± 1.7 and 16.4 ± 2.0 for passive and Kegel profiles, respectively. There were no significant changes in functional urethral length in either the effective or ineffective group. Table I compares the changes between the passive and Kegel profiles for the two groups. As expected, there were highly significant differences between the two groups for the changes in all profile measurements.

As demonstrated in Table II, there were no significant differences between the effective and ineffective Kegel effort groups with respect to age, parity, weight, or any of the passive profile measurements. Likewise, there were no significant differences between the groups with respect to the prevalence of prior continence surgery, prior hysterectomy, severe pelvic organ prolapse, hypoestrogenism, or genuine stress incontinence. When the ability to perform an effective Kegel contraction was compared to urodynamic diagnosis, no clear pattern was seen; 57% of patients with pure genuine stress incontinence (8/14), 67% with mixed incontinence (4/6), 75% with pure unstable urethra (3/4), 33% with pure detrusor instability (1/3), 60% with vaginal vault prolapse (3/5), 100% with emptying phase dysfunction (4/4), and 50% with no abnormal diagnosis (5/10) were able to generate an effective Kegel effort.

Twelve subjects (26%) had increases in vesical pressure >15 cm H_2O during the Kegel contraction, 5 in the effective effort group and 7 in the ineffective effort group (difference not statistically significant). The change in vesical pressure (mean ± SE) for those with excessive Valsalva effort was 39.8 ± 12.5 cm H_2O in the effective Kegel group and 21.6 ± 4.6 cm H_2O in the ineffective Kegel group. The respective changes for those without excessive Valsalva effort were 5.9 ± 2.1 and 6.5 ± 1.2 cm H_2O. Four of the five subjects with improvement in urethral measurements after Valsalva effort had either prior successful continence surgery or severe pelvic organ prolapse, conditions in which Valsalva stress is known to enhance urethral closure because of physical obstruction.[6, 7] As anticipated, there was a highly significant correlation between the changes in vesical and vaginal pressures during the Kegel effort ($r = 0.8306, p < 0.00001$).

Comment

This study has demonstrated that 60% of the 47 subjects were able to generate an effective increase in the force of urethral closure after brief standardized verbal instruction. However, 5 of 28 subjects with an effective Kegel effort achieved this with an appreciable increase in abdominal and vaginal pressure. Thus only 23 of 47 subjects (49%) had an ideal Kegel effort, that is, a significant increase in urethral pressure without a concurrent increase in vesical and abdominal pressure. Moreover, we were unable to identify any historic or urodynamic parameter that reliably identified subjects who were likely to have either an effective or an ineffective Kegel effort. These included age, parity, weight, prior continence surgery, prior hysterectomy, severe pelvic organ prolapse, any parameter on a passive urethral pressure profile, and any urodynamic diagnostic category.

It is recognized that our criteria for an effective Kegel contraction were arbitrary, but this was necessary because no criteria have been previously established. In defense of our criteria, it should be emphasized that very few subjects in either group came close to our cutoff values. For example, only one subject in the ineffective group increased the total profile area by >8% and 13 of 19 subjects in this group actually decreased the profile area with the Kegel effort. In contrast, only 4 subjects in the effective group had <20% increase in total profile area; they had increases in maximum and mean urethral closure pressures that averaged 31% and 46%, respectively. The lack of change in profile area in these subjects was due to a decrease in functional urethral length that averaged 28%. We thought this resulted from urethrovesical junction movement (elevation) away from the urethral transducer during the Kegel profile, the net effect of which would be an increase in the speed of withdrawal of the urethral transducer relative to the paper speed of the recorder. We attempted to have the Kegel contraction established before catheter withdrawal to obviate this technical problem; however, this goal obviously was not realized in these four subjects.

Genuine stress incontinence (No.)	12 (43%)	8 (42%)

We also recognize that the small number of subjects in some of our groups limits the power of any conclusion regarding the lack of effect of certain factors on the ability to perform an effective Kegel contraction. However, it is clear that none of these factors guarantees either success or failure. Fig. 2 contains tracings from three subjects that illustrate these points vividly. Part *2A* is a passive and Kegel urethral pressure profile from a 62-year-old, para 5 woman with recurrent mixed incontinence, a prior hysterectomy, and a Marshall-Marchetti-Krantz procedure. She was post-

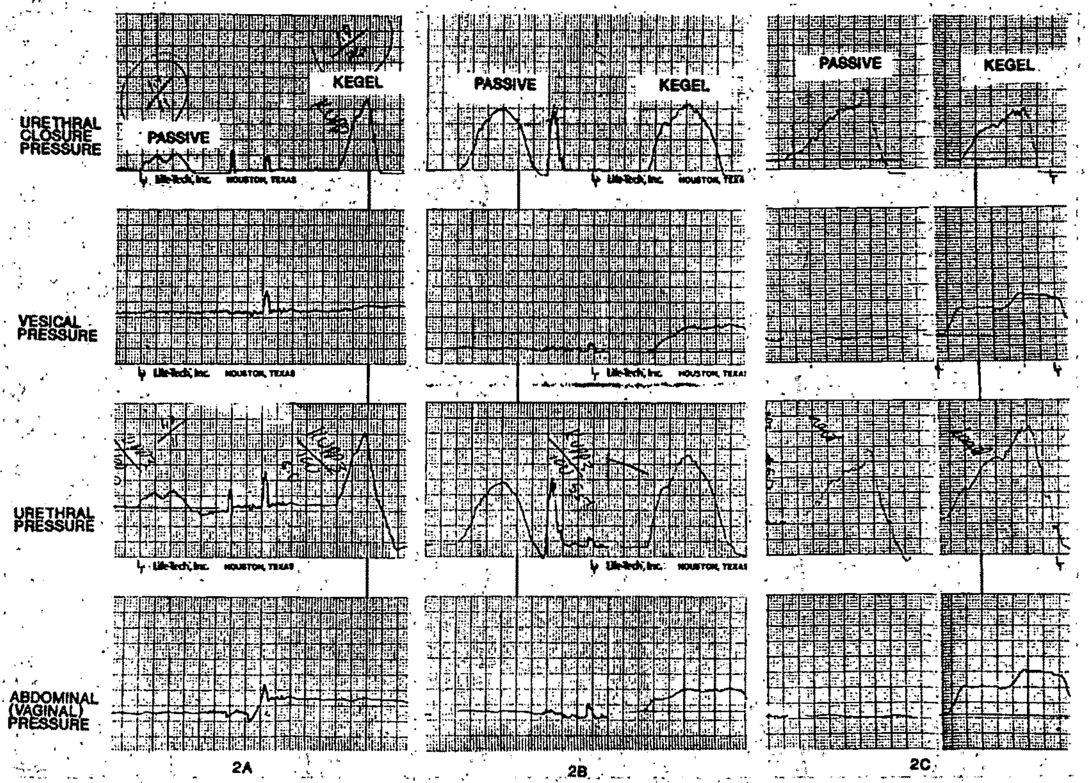

Fig. 2. Tracings of passive and Kegel urethral pressure profile of three subjects. See Comment section for details. **2A,** 62-year-old, multiparous subject with effective Kegel effort; **2B,** 27-year-old nulliparous subject with ineffective Kegel effort and significant Valsalva effort; **2C,** 52-year-old multiparous subject with genuine stress incontinence whose Valsalva effort with Kegel attempt resulted in decrease in force of urethral closure.

menopausal for 14 years but had never received estrogen replacement therapy. The passive profile demonstrated a markedly hypotonic urethra with a functional urethral length of 17 mm and a maximum urethral closure pressure of 11 cm H_2O. In spite of a variety of factors that led us to intuitively believe that she would be unable to display an effective Kegel contraction, she was able to increase the total profile area, maximum urethral closure pressure, and mean urethral closure pressure by 186%, 318%, and 170%, respectively. In contrast, part *2B* is a tracing from a 27-year-old nulliparous woman with sensory urgency, normal ovarian function, and no prior urogynecologic survey. In spite of characteristics that we believed would predict an effective Kegel effort, the only effect of her Kegel effort was a 15 cm H_2O increase in vaginal and vesical pressure with no appreciable change in urethral closure pressure.

Part *2C* illustrates a potential danger of incorrectly performed Kegel exercises. This tracing is from a 52-year-old, gravida 2 woman with primary pure genuine stress incontinence. Her Kegel effort was accompanied by a significant Valsalva effort with an increase in vaginal and vesical pressure of nearly 30 cm H_2O. This increase in abdominal pressure was transmitted only partially to the urethra with the net effect being a decrease in total profile area, maximum urethral closure pressure, and mean urethral closure pressure of 32%, 28%, and 11%, respectively. Thus, instead of improving the force of urethral closure, the Kegel technique actually had the opposite effect. Further, a structured program of regular repetition of this technique might actually lead to progression of the anatomic and functional defect that is the cause of incontinence in this woman.

This study offers no insight into the predictive value of the Kegel urethral pressure profile. We do not know if an effective Kegel effort by a woman predicts successful control of incontinence if she pursues a structured Kegel exercise program, nor do we know if ineffective Kegel efforts can be made effective through reeducation and the use of biofeedback. Finally, we do not know if an improvement in the force of urethral closure with a Kegel contraction will correlate positively with an improvement in urinary control. These are all topics of ongoing inquiry in our unit.

What does seem obvious from this study is that simple verbal or written instruction does not represent adequate preparation for a patient who is about to pursue a Kegel exercise program. While approximately half of women are able to perform an effective contraction, half are not and as many as one fourth may adopt a technique that could potentially promote the defect responsible for their incontinence. Some form of initial assessment, instruction, and feedback such as pubococcygeal and abdominal muscle palpation with verbal feedback, the use of differential (upper vagina reflecting abdominal pressure and lower vagina reflecting levator tone) vaginal pressure biofeedback, or the use of electromyographic biofeedback seems desirable. Saving such techniques only for Kegel failures needlessly postpones potentially effective therapy for a significant number of women who suffer from incontinence. In addition, many women who feel that they have failed their initial trial with a Kegel exercise program will refuse to accept any additional physiotherapy.[8]

Discussion

DR. A. CULLEN RICHARDSON, Atlanta, Georgia. I congratulate the authors on a very carefully done study with carefully recorded exact data. It is encouraging to see attention returned to the striated muscle in the pelvis. We need to understand more about its role in pelvic support in general, as well as in urinary continence.

My principal criticism of this article is that at this point I consider it to be an incomplete study. This is an excellent first step in a much-needed investigation of Kegel exercises, but the data contained in this study, although excellent, are not sufficient to permit significant conclusions.

The study lacks a control group of perfectly normal nulliparous and parous patients. Patients presenting to a urodynamics clinic are hardly a representative patient population. These results are not applicable to the general population.

The authors concluded that simple verbal instruction does not represent adequate preparation for a patient who is about to start a Kegel exercise program. However, they did not report how many of those who had no change in urethral closure pressure were eventually taught to sustain good levator contractions.

There were variables for which there were no corrections.

At the beginning the authors made an assumption: "Implicit to our understanding of the physiologic basis of Kegel exercises is that a properly performed contraction should increase the force of urethral closure." This would be true only in patients with perfectly normal anatomy, which few of their patients had.

Potentially, there are two anatomic variables that must be controlled for that were not addressed in this article. As this is essentially a test of isolated striated muscles, normal function would require, first, structural integrity of the muscle itself and its attachment and, second, intact neurologic innervation of the particular muscle being studied.

The effect on urethral pressure with voluntary contraction of the pelvic floor muscle is exerted through three groups of striated muscle fibers. First and most prominent is the pubovaginal portion of the pubococcygeus muscle (fibers of Luschka). Second, there are the very thin, roughly circular striated periurethral fibers that terminate in the musculus transversus perinei profundus of the urogenital diaphragm. Third are the fibers in the musculus transversus perinei profundus that go over the top of the urethra just as it passes under the symphysis (so-called compressor urethra muscle). In the case of the pubovaginal fibers of Luschka, the force is not on the urethra itself but is transmitted by way of the pubocervical fascia within which the urethra is embedded.

If these striated muscle fibers are detached from the vagina or the paraurethral fascia is broken, then even with good pubococcygeus contraction there would be no effect on urethral closure pressure. As the authors continue their study, there should be a control for pubococcygeus contractions, with fine-wire electromyography, to identify those patients who in spite of pubococcygeal contraction show no change in urethral closure pressure. I am sure these patients exist.

Even in patients whose muscles are intact, there can be a problem with neurologic innervation. This of course can extend from the cerebral cortex down through the cord and then through the peripheral nerves to the myoneural junction. The assumption in the study seemed to be that all of the problems were at the level of the cerebral cortex—failure to understand the instructions.

There is increasing evidence that many patients with genital support problems with or without bladder dysfunction manifest weakness in the pelvic floor striated muscle as a result of deficient or damaged neurologic innervation—a problem not particularly affected by exercise.

Gilpin et al.[1] and Smith et al.[2,3] in Manchester, England, Snooks et al.[4] in London, and Constantinou and Govan[5] in this country have studied and are studying this in depth. They have found some women whose problem is in the peripheral nerves at the spine as a result of bony deformities such as are seen with spondylitis, many in the pudendal nerves as a result of stretch injury during parturition, and some with stretch injury within the muscle itself.

This becomes even more complicated when one considers that the pelvic floor striated muscle contains both slow- and fast-twitch fibers. The slow-twitch fibers, which are quite prominent in the pelvic floor muscles, maintain some constant involuntary tone, much as is the case with the external anal sphincter. Undoubtedly the resting tone of these slow-twitch fibers in the levator group is the important factor in keeping the levator hiatus essentially closed in the patient with normal support.

Normal pelvic support is always a delicate interplay between the fibrous connective-type tissues and striated muscle tone—involuntary, reflex, and voluntary. Mechanically, the striated muscles not only serve as a backup mechanism to protect the overlying connective-type tissues (the fascias and ligaments) but are actually the mediators of certain functions, such as aiding in the closure of the bladder neck, as well as the anal sphincter. As yet we have no medical or good surgical treatments for inadequate striated muscle function.

We all tend to recommend Kegel exercises rather routinely. These would be ineffective, however, if the problem is one of neurologic change. Further, the authors have apparently identified a subset of patients in whom the exercises are not only ineffective but potentially deleterious.

Again I congratulate the authors on carefully recording these preliminary observations. My hope is that they will continue to study the pelvic floor striated muscle with normal controls, electromyographic monitoring of the pubococcygeus, and a careful record of the anatomic findings. Clearly their preliminary results confirm the need for much better understanding. Further, their study makes it clear that we need a better method of instructing patients in the "how to" of Kegel exercises.

I would ask them several questions at this time:

1. Do you have data that you did not include that would answer the questions posed?

2. What percent of patients were able to effect good levator contractions after more detailed instructions and/or some biofeedback?

3. At present, what have you found to be the best "how to" in instructing patients for Kegel exercises?

It is hoped that these authors, who possess the expertise to do such careful and exact studies, will continue their efforts and give us the much-needed additional data to clarify the preliminary findings reported here.

Dr. Bump (Closing). With respect to the appropriateness of our study group, I would defend our population as exactly representative of the types of patients who are started on a Kegel exercise program. Therefore the information is directly applicable to the portion of the population that might start such a program. Kegel advocated his exercises for patients who needed to improve the function and tone of the pelvic floor, that is, after childbirth, with early cystocele and rectocele, and with incontinence. I should also mention that our incidence of ineffective Kegel effort corresponds with that of several other authors in the physiotherapy literature.

I don't doubt that some of our ineffective contractors were ineffective not because they did not understand which muscles to contract but because the muscles or the connective tissue attachments were rendered incapable of responding. However, our findings do not support this as the primary reason for failure, because subjects who were most likely to have such neuromuscular and anatomic compromise were able to perform just as well as subjects who had no evidence of such injury. Further, a significant proportion of subjects were not simply ineffective; nearly one quarter had efforts that were counterproductive.

With respect to Dr. Richardson's question of clandestine data that may address the questions as to the type and location of striated muscle involved in the continence mechanism, we are in the process of completing a study that confirms and expands on the findings in the studies of the groups he mentioned. One of our major research priorities is to develop techniques to study denervation injury and recovery. By way of drastic oversimplification I would simply state that there is no question in my mind that there are critical neuromuscular components to stress incontinence in women and that simple anatomic alterations do not explain the condition.

As to our eventual ability to teach ineffective contractors to become effective and the best way of providing instruction for Kegel exercises, I hope that our groups' efforts, under the primary direction of Dr. Jean Wyman, will allow us to answer that question, but the answer is 4 to 5 years away.

I think the worst way to instruct patients is to ask them to interrupt the urinary stream repeatedly during micturition. I have three primary aversions to this time-honored technique. First, many women, and most incontinent women, cannot interrupt the stream, and asking them to do what they are unable to do simply accentuates their feelings of helplessness and hopelessness. Second, I don't think that the way you improve the bladder's storage ability is by interfering with its emptying function. A contracting sphincter in the midst of normal micturition is a pathologic condition known as vesicosphincter dyssynergia, and I don't think we should encourage patients to practice this technique. Remember, we can entrain our bladders to adopt bad habits in addition to good ones. Finally, when the completely normal woman interrupts the urine stream, the urethral closure pressure becomes positive and flow stops several seconds before the detrusor muscle contraction is suppressed. This detrusor contraction against a voluntary outlet obstruction several times during every voiding episode may result in reflux and eventually upper tract injury.

Vulvar squamous cell carcinoma and papillomaviruses: Two separate entities?

Willie A. Andersen, MD,[a] Douglas W. Franquemont, MD,[b] John Williams,[b]
Peyton T. Taylor, MD,[c] and Christopher P. Crum, MD[a, b, c]
Charlottesville, Virginia

Vulvar squamous precancers (vulvar intraepithelial neoplasia) are associated with sexual factors, cigarette smoking, and human papillomaviruses. However, epidemiologic studies of invasive carcinoma of the vulva have produced conflicting evidence for these associations, in part because of a strong association with vulvar inflammatory disease (dystrophies) in older women. We analyzed a series of 42 vulvar invasive carcinomas for papillomavirus nucleic acids by deoxyribonucleic acid–deoxyribonucleic acid in situ hybridization and correlated their presence with age, smoking history, and morphologic type. The carcinomas were divided into well-differentiated, moderately and poorly differentiated, and intraepithelial-like growth patterns, the latter composed of nests of invasive neoplastic epithelium with preserved cell polarity, similar to intraepithelial disease. Of the lesions studied, 28% were human papillomavirus deoxyribonucleic acid–positive. Intraepithelial-like neoplasms segregated in women with a younger mean age (64 versus 73 years) than that of women with conventional squamous cell carcinoma and they more frequently had a history of cigarette smoking (88% versus 28%). Moreover, intraepithelial-like lesions contained human papillomavirus nucleic acids more frequently (67% versus 13%) when analyzed by in situ hybridization. These observations confirm the diverse nature of vulvar squamous cell carcinoma and may explain in part why conflicting results are obtained from studies investigating the role of sexual and viral factors in the genesis of vulvar cancer. They suggest that many invasive vulvar cancers may not be linked to papillomaviruses. (Am J Obstet Gynecol 1991;165:329-36.)

Key words: Vulvar carcinoma, human papillomavirus, vulvar intraepithelial neoplasia

Invasive carcinoma of the vulva is a rare disease with an incidence rate approximately one tenth that of its counterpart in the cervix.[1, 2] Traditionally the disease has predominated in women in their seventh and eighth decades and is rarely observed in women younger than age 30 years.[2] This pattern of disease has changed slightly in recent years, and investigators have focused on three components of this disease spectrum that may shed light on the increasingly younger age of women seen with vulvar neoplasia. The first is the oc-

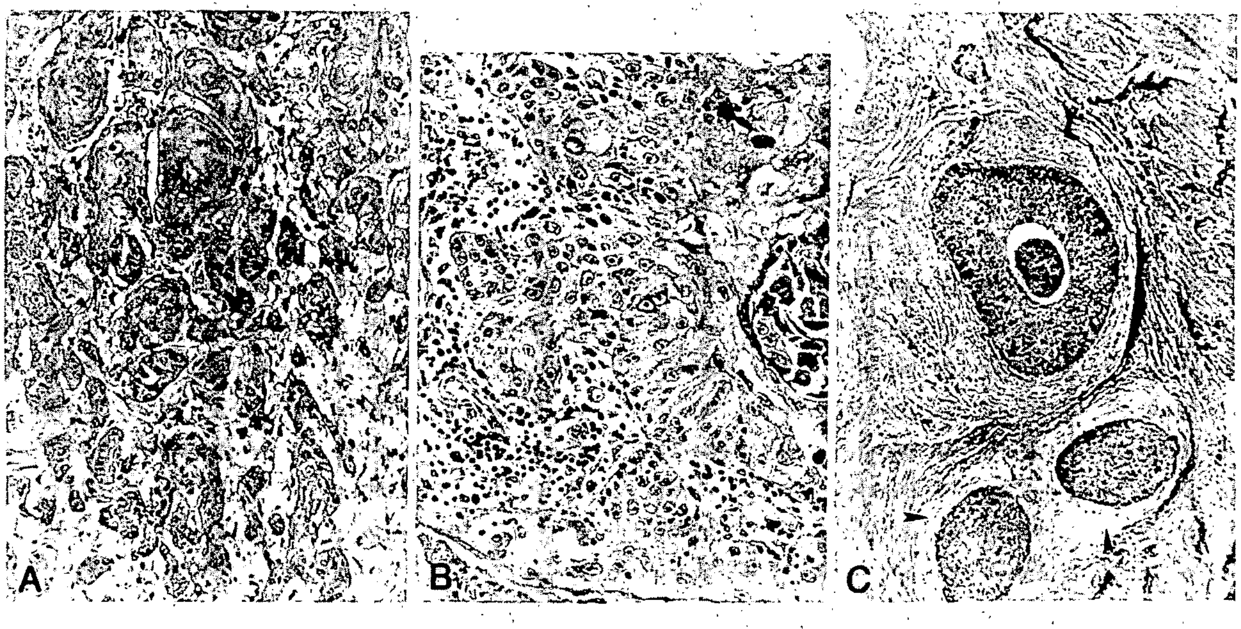

Fig. 1. Histologic subgroups studied. **A,** Well-differentiated keratinizing squamous cell carcinoma of the vulva; **B,** moderately to poorly differentiated squamous cell carcinoma of the vulva; **C,** intraepithelial-like squamous cell carcinoma of the vulva. Note the well-circumscribed nesting pattern of the tumor cells, similar to a precursor (vulvar intraepithelial neoplasia) lesion. The adjacent desmoplastic stromal changes *(arrows)* indicate that this is invasive cancer and not a tangentially sectioned vulvar intraepithelial neoplasia.

currence of vulvar precancers, or vulvar intraepithelial neoplasia, which are occurring more frequently in younger women and carry some risk of evolving into cancer as a function of increasing age.[3-6] The second is the human papillomavirus (HPV), which has been increasingly associated with cervical precancerous lesions and linked with vulvar intraepithelial neoplasms as well.[7] The third is the subset of squamous carcinomas, which are separated from their noninvasive counterparts by several decades, are infrequently associated with vulvar intraepithelial neoplasia, and appear to be more associated with vulvar inflammatory conditions than with sexually transmitted diseases.[8-10]

The potential discrepancy between sexual factors and vulvar cancer has been magnified by epidemiologic studies of vulvar carcinoma. Although vulvar neoplasia has been linked to sexual factors by some authors,[11-13] and a case-control study of vulvar carcinoma identified preexisting genital warts and smoking as singificant risk factors,[11] others have found little relationship between sexual factors and invasive vulvar carcinoma. Mabuchi et al.[9] failed to associate early age of coitus, first marriage and multiple miscarriages, or venereal factors with vulvar cancer.[9] They observed a relationship to prior history of vulvar inflammation and urogenital cancer, whereas the relationship to prior cervical cancer (six cases of 149) was of borderline significance.[9]

Those studies suggest that, from an epidemiologic perspective, vulvar cancer may encompass more than one distinct group. Additional evidence that vulvar carcinomas have a diverse pathogenesis comes from two morphologic studies that examine the epithelium adjacent to invasive vulvar cancers. Both Buscema et al.[8] and Zaino et al.[10] noted that in only approximately one fourth of invasive cancers was there evidence of a classic vulvar intraepithelial neoplasm (carcinoma in situ) in the adjacent epithelium. In contrast, more than one half of cases were associated with epithelial hyperplasia or atrophy and inflammation, with or without cytologic atypia (lichen sclerosis, squamous hyperplasia, atypia).[9, 10] These findings suggested that a significant proportion of vulvar carcinomas did not evolve from a long-standing precancerous lesion. It is important that cancer developed in only a fraction of women with chronic inflammatory diseases of the vulva.[14]

One recent study[15] corroborated the above observations, noting a variable detection rate of HPV nucleic acids in vulvar cancer. It is important that these authors[15] observed a strong relationship between smoking and women with HPV-related vulvar precancers versus squamous carcinomas, the majority of which had an associated vulvar intraepithelial neoplasia. Moreoever, another study has reported an absence of HPV nucleic acids in a small series of vulvar carcinomas associated with chronic inflammatory vulvar disease (lichen sclerosis) rather than with vulvar intraepithelial neoplasia.[16] From this it would appear that different subsets of cancers exist, and an association with vulvar

intraepithelial neoplasia may identify a group epidemiologically distinct from other invasive cancers.

In this study, we analyzed a series of vulvar resections from 42 women with squamous cell carcinoma of the vulva. Our goal was to determine the frequency of detection of HPV nucleic acids and whether this parameter could be related to age, morphologic growth pattern, smoking history, and clinical behavior. We show that HPV nucleic acids are preferentially associated with a specific morphologic subtype of vulvar carcinoma and that this subtype is significantly associated with a younger age population and smoking history vis-a-vis other squamous cell carcinomas of the vulva.

Material and methods

Hypotheses to be tested. We intended to determine the proportion of conventional invasive cancers that were not associated with HPV nucleic acids and whether a subset of such patients would be distinguished by virtue of one or more morphologic, clinical, or behavioral parameters from the patients whose lesions were associated with HPV.

Patient selection and clinical data. From January 1978 to December 1987 the pathologic records of all women evaluated and treated for vulvar squamous cell carcinoma at the University of Virginia Health Sciences Center were reviewed. Retrospective chart review was performed and pertinent clinical data abstracted and entered for statistical analysis. Data obtained included age, smoking history, clinical stage of carcinoma, and survival. All histologic material was retrieved where possible, and cases with paraffin-embedded tissue were selected.

Histologic analysis. Cases were segregated into three morphologic categories: (1) Well-differentiated keratinizing (11 cases), (2) moderately and poorly differentiated (19 cases), and (3) intraepithelial-like (12 cases) squamous cell carcinoma. The latter contained areas of invasive neoplasm with a growth pattern similar to that of intraepithelial neoplasia (i.e., the cells were arranged in concentric nesting patterns with peripheral palisaded nuclei; Figs. 1 and 2).

Analysis for HPV nucleic acids. Serial sections from each tumor were analyzed for HPV nucleic acids by DNA-DNA in situ hybridization with biotinylated probes (for HPV types 6/11, 16/18, 31/33/35; VIRATYPE, Life Technologies, Gaithersburg, Md.). Because the goal was to determine whether HPV nucleic acids were present rather than determine specific type, hybridizations were carried out under conditions similar to those recommended by the manufacturer, with posthybridization washes performed at 42° C. Under these conditions, HPV type 16/18 DNA probes produced positive hybridization signals with formalin-fixed paraffin-embedded HeLa cells, which contain 10 to 20 copies of HPV type 18 DNA.

Statistical analysis. Statistical analysis was performed with a p value of 0.05 or less for statistical significance. Ordinal data were analyzed with comparison of median values with the Mann-Whitney U test; ratio data were analyzed with the Student t test; nominal data were analyzed with either χ^2 or Fisher's exact test. Kaplan-

Meier actuarial survival curves were compared with the Z scores.

Results

Clinical data. Forty-two cases were selected on the basis of the availability of material for histologic and viral analysis. Thirty-six were white and six black, and the ages ranged from 44 to 90 years with a mean of 69.1 ± 11.3 years and a median of 70 years. Gravidity ranged from 0 to 9 with a median of 3 (Table I).

From chart review it could be determined that 12 of the 42 women had a history of current or past tobacco use, with 14 known definitely to have never smoked. The smoking history of the remaining 16 patients could not be determined (Table I).

Tumor stage at initial presentation was as follows: International Federation of Gynecology and Obstetrics classification (FIGO) stage I, eight patients; stage II, 13 patients; stage III, 15 patients; and stage IV, six patients. Thirty-two women were treated by surgery alone, three by a combination of surgery and radiation, and the remaining seven by radiation alone (Table II).

Patients treated by surgery alone included six with radical vulvectomy, two with radical vulvectomy and unilateral groin node dissection, 22 with radical vulvectomy and bilateral groin node dissection, one with radical vulvectomy and abdominoperineal resection of the rectum and perineum, and one with radical vulvectomy and abdominoperineal resection of the rectum and perineum and unilateral groin node dissection (Table II).

Of the 28 patients with either unilateral or bilateral groin node dissections (with or without irradiation), 17 were found to have negative lymph nodes, seven had positive ipsilateral groin nodes, three had positive bilateral groin nodes, and one had a positive retroperitoneal (Cloquet's) node.

The adjusted actuarial survival rate for the 42 patients at 5 years was 81.4% (±6.4%). The FIGO stage I patients had an adjusted actuarial survival rate of 100% at 5 years, with 91.7% (±7.9%), 72.2% (±11.8%), and 60.0% (±21.9%), adjusted actuarial survival rates for stages II, III, and IV, respectively (Fig. 3).

Histologic analysis. Of the 42 cases, 11 were well-differentiated keratinized tumors, 19 were moderately to poorly differentiated, and 12 were intraepithelial-like. Coexisting vulvar intraepithelial neoplasia was found in none, none, and 33% of the above groups, respectively. Clinical features that correlate with these subtypes are summarized in Table I. Patients in the intraepithelial-like subgroup were significantly younger ($p = 0.04$) than the other groups. In addition, a significantly higher proportion of the intraepithelial-like subgroup reported a history of smoking than that of the other two groups ($p = 0.01$). Race and gravidity were not associated significantly with histologic subtype.

HPV DNA analysis. Twelve of 42 cases were positive for the presence of HPV DNA. Although the precise HPV type could not be determined because of the low stringency of hybridization, the strongest signals in each case were obtained with the HPV type 16/18 or HPV type 31/33/35 probes or both. The association of HPV DNA with histologic subtype is summarized in Table III and illustrated in Fig. 2. The intraepithelial-like carcinomas were significantly associated with HPV DNA ($p = 0.002$) vis-a-vis the other types. The likelihood of a lesion being HPV-positive was also associated with higher gravidity ($p = 0.05$) but not with a younger age ($p = 0.2$).

There was no correlation between survival and HPV DNA positivity. There was, however, bias in the groups because there was a statistically significant unequal distribution of treatment types between the HPV-positive and HPV-negative patients. Ninety percent (27/30) of the HPV-negative cases were treated by surgery alone in contrast with 6 of 12 (50%) HPV-positive cases that were treated with either radiation and surgery or radiation alone ($p = 0.01$). This bias was also reflected in an unequal distribution of treatment types as associated with histologic subgroup. Although 26 of 30 (86%) of the cases of well-differentiated keratinizing or moderately to poorly differentiated tumors were treated with surgery alone, only 6 of 12 (50%) of the intra-

epithelial-like group were managed exclusively by surgery.

Comment

Although it has been assumed that a large proportion of invasive cervical carcinomas evolve from intraepithelial precursor lesions, the data in support of this mechanism for the development of vulvar cancer have been conflicting. Most compelling has been the marked disparity in the mean ages of women with vulvar intraepithelial neoplasia versus invasive cancer.[1-3] Moreover, several studies have reported that the majority of vulvar carcinomas are not associated temporally or topographically with typical precursor lesions such as vulvar intraepithelial neoplasia, but with hyperplastic or inflammatory epithelial changes (dystrophies) with various grades of cytologic atypia.[8, 10]

Because papillomaviruses and sexual factors have been closely associated with vulvar intraepithelial neoplasia, attention has naturally focused on the relationship between these factors and invasive cancer. However, both sexual and nonsexual causes have been proposed. For example, Mabuchi et al.[9] observed little relationship between invasive vulvar carcinoma and a history of condylomata. In contrast, these authors[9] found a relationship between vulvar carcinoma and occupational exposures, caffeine consumption, and smoking in younger women. A different perspective

was put forth by Brinton et al.[11] who reported a powerful association between a history of condylomata or smoking and both vulvar intraepithelial neoplasia and invasive vulvar carcinoma. These authors[11] concluded that sexually transmitted agents occupied a central place in the pathogenesis of vulvar cancer.

A simple resolution of the disparity between the conclusions provided by the studies described here is problematic. However, it is noteworthy that the population studied by Mabuchi et al.[9] included a higher proportion of women older than 55 years of age than that of Brinton et al.[11] Thus it is likely that Mabuchi et al.[9] studied a population of which a larger proportion did not have associated intraepithelial disease. Indirect support for this is the much stronger association of vulvar neoplasia with smoking by Brinton et al.[11] in that this risk factor has been associated both with vulvar intraepithelial neoplasia and a younger age population.

The association between papillomaviruses and vulvar neoplasia has likewise been inconsistent and controversial. Although HPV type 16 nucleic acids have been strongly associated with intraepithelial neoplasia in several studies, the association between HPV nucleic acids and invasive carcinoma is weak.[7,15,17] Twiggs[17] observed that only 17% of invasive vulvar carcinomas were positive by in situ hybridization, similar to the results of this study. A possible link between HPV positivity and smoking in vulvar carcinoma has been observed.[15] Combined with the strong association between smoking and vulvar intraepithelial neoplasia, this suggests that one population of vulvar cancers may be identified by a strong smoking history, coexisting vulvar precursors, a younger mean age, and the presence of papillomavirus nucleic acids, implying in turn the role of sexual factors. This study supported this with the additional observation that most vulvar carcinomas associated with HPV nucleic acids were recognizable by the presence of certain morphologic features that resembled intraepithelial disease, even when a coexisting precursor (VIN) lesion was not identified.

In contrast, evidence has begun to accumulate that cancers that are not associated with vulvar intraepithelial neoplasia, and specifically those associated with vulvar inflammatory conditions such as lichen sclerosis, are infrequently associated with HPV nucleic acids.[16] Combined, these data strongly suggest at least two different pathogenetic mechanisms for vulvar squamous cell carcinoma.

It remains to be confirmed whether pathologic analysis will segregate the majority of HPV-related vulvar neoplasms from those that are not. However, the observations in this report combined with the negative association between coexisting lichen sclerosis and HPV-related carcinomas support the use of both viral and histologic parameters in epidemiologic studies of vulvar carcinomas. Such studies may be instrumental in placing the role of viral sexual factors in proper perspective and in targeting other risk factors associated with a large proportion of vulvar carcinomas in older women.

Discussion

DR. FRED T. GIVEN, JR., Norfolk, Virginia. Dr. Andersen et al. address the association of the HPV and invasive squamous cell carcinoma of the vulva and correlate this with age, smoking history, and morphology. For my comments I am indebted to the expertise of two of my colleagues at the Eastern Virginia Medical School, Dr. Ken Somers, Professor of Microbiology and Immunology, and Dr. Jeng G. Hsiu, Associate Professor of Pathology. The primary goal of the authors was to determine by the use of in situ hybridization the frequency of association of the HPV and the correlation of this occurrence with specific morphologic types of vulvar cancer as well as age and smoking history. The evidence presented is interpreted to show that HPV DNA is preferentially associated with a specific morphologic subtype of vulvar carcinoma (intraepithelial-like lesions) and that the intraepithelial-like subtype is associated with a younger mean age and a positive smoking history. The results of this study are only as good as the sensitivity of the assay for the HPV DNA. The in situ hybridization assay used to detect HPV DNA in this article is the only method that allows precise microscopic detection of HPV nucleic acids within cells. The major drawback of the in situ test is its reduced sensitivity, relative to Southern blot or dot blot hybridization in the detection of latently HPV-infected tumors. Latently infected tumors or adjacent normal epithelium would likely receive a negative score in the in situ assay. Therefore the absence of HPV DNA in vulvar squamous cell carcinoma does not exclude an HPV etiologic factor. It is also important to note that negative HPV DNA results only mean that the test is negative for the HPV types evaluated.

The morphologic interpretation and proposed histologic criteria of intraepithelial-like invasive squamous cell carcinoma of the vulva in this article includes nests of invasive neoplastic epithelium with preserved cell polarity, similar to intraepithelial disease. This definition seems to create some confusion and uncertainty for the following reasons: (1) Vulvar intraepithelial neoplasia represents a continuous morphologic spectrum of epithelial cellular abnormality and maturation. Vulvar intraepithelial neoplasia is divided into types I, II, and III. Do the authors mean the intraepithelial lesion mimics vulvar intraepithelial neoplasia type III? It would seem difficult to classify the intraepithelial-like invasive squamous cell carcinoma into a separate distinct morphologic entity on the basis of their proposed criteria. (2) It is also known that invasive squamous cell carcinoma of the vulva is composed of a heterogeneous morphologic pattern of neoplasia, even within the same tumor. Focal areas of vulvar invasive squamous cell carcinoma may fit into the author's criteria of intraepithelial-like growth pattern, but other areas of the same

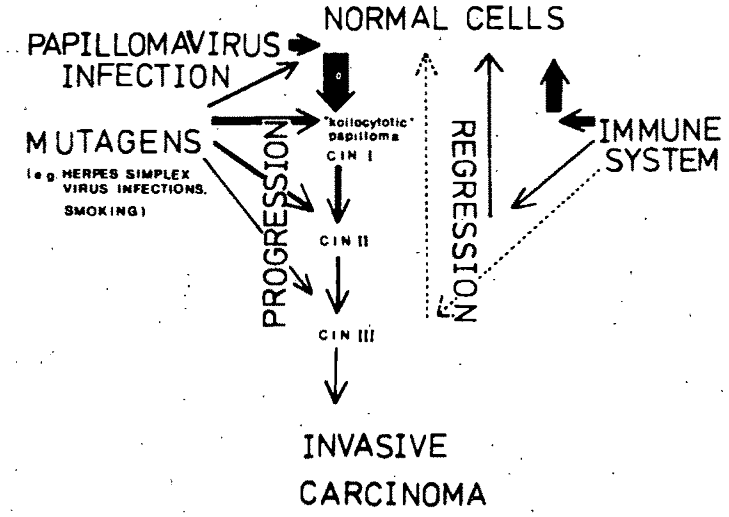

Fig. 1. Proposed model for synergistic effects in human genital cancer. (From zur Hausen H. Lancet 1982;2:1371. By permission.)

tumor may show a totally different morphologic growth pattern. How will the authors clarify such squamous cell carcinomas that comprise different patterns?

The data on smoking cause me some concern and that concern is confounding. This was well pointed out in an editorial.[1] There may be many other initiating events or promoting factors in the cause of vulvar cancer, just as there are in carcinoma of the cervix. This is certainly well illustrated in the model proposed by Dr. zur Hausen (Fig. 1).[2]

The author's data certainly seem to show some association between the papillomavirus and intraepithelial-like carcinoma of the vulva. This seems to occur at a somewhat younger age; however, it remains to be seen whether survival is affected by being able to isolate this particular subgroup of patients. Is the biologic behavior of the intraepithelial-like lesion described by the authors different? This study should be repeated with an even more sensitive technique, specifically, polymerase chain reaction amplification of HPV DNA with primers that recognize highly conserved regions within the HPV genome.[3] Until these data are presented, negative results should be interpreted with caution. There should also be adjustment for confounding, such as the sexual activity, number of partners, exposure to passive smoke and caffeine if they want to truly see the effects of smoking per se on the epidemiology of carcinoma of the vulva. We believe this study should be continued in much more detail and with a larger number of patients, perhaps requiring a multiinstitutional protocol to confirm these preliminary results.

I have three questions for Dr. Andersen:

1. Do you believe that you will be able to classify the intraepithelial-like invasive squamous cell carcinoma of the vulva in a heterogenous type of neoplasm?

2. Do you believe that with a much larger series the group with the intraepithelial-like growth pattern will have a different survival rate than other invasive squamous cell carcinomas of the vulva?

3. Are you convinced of the significance of the smoking data with a series this small?

Dr. Matthew O. Burrell, Atlanta, Georgia. Did the authors have any cases with preexisting or coexisting lichen sclerosis? In Atlanta we have had four patients in whom early invasive carcinoma has developed in preexisting lichen sclerosis.

Dr. Andersen (Closing). We looked at the surrounding epithelium in most cases and four of 12 with an intraepithelial-like pattern had associated vulvar intraepithelial neoplasia. Eight of the remaining 28 were associated with some other form of vulva dystrophy. We had one of the 42 in whom an invasive cancer developed while being folowed up for vulvar dystrophy. Therefore I think vulva dystrophies demand careful attention and follow-up.

To address Dr. Given's comments and concerns, it is Dr. Crum's belief that the intraepithelial-like pattern can be distinguished by the orientation of the cells in circumscribed nests with retention of cell polarity and palisaded nuclei at the periphery (Figs. 1, *C*, and 2, *A*). This arrangement of cells is similar to that seen in vulvar intraepithelial neoplasms, irrespective of grade, but cannot be compared directly with them gradewise because this pattern is being described in invasive carcinomas. In all the intraepithelial-like lesions, this growth pattern was clearly present in an invasive component by virtue of the stromal reaction around the nests (Fig. 1, *C*). We agree that lesions may be heterogeneous and contain more than one pattern, but the intraepithelial-like pattern was classified separately because of its distinctive appearance. The association of HPV nucleic acids with intraepithelial-like neoplasms may be fortuitous or reflect the fact that invasive carcinomas within this growth pattern are more likely to have derived from vulvar intraepithelial neoplasms. As you know, a high percentage of the latter are known to contain genital papillomavirus nucleic acids.

Whereas a variety of other techniques have been used to search for HPV DNA in human cells, we believed in this retrospective study that the in situ hybridization technique was the most appropriate because it provided for direct localization of HPV nucleic acids in the cells of the neoplasm. The polymerase chain reaction, although superior in sensitivity, does not establish the location of the viral nucleic acids detected and can be plagued by false-positive results. I would reemphasize that the hybridization conditions used by Dr. Crum permitted detection of not only HPV DNAs identical to those in the probes, but more distantly related HPV types as well, and the sensitivity was such that as few as 10 to 20 copies of HPV DNA could be detected in an individual cell.

Our smoking data were based purely on chart review and in many instances we could not tell whether the patients had ever smoked. The issue of smoking exposure is quite complex and although in our small series with small numbers we can show a statistical association between smoking and intraepithelial-like histologic pattern as well as the presence of HPV, clearly this is only a preliminary observation that requires much more sophisticated epidemiologic study to confirm this potential association.

Treatment failure of genital condylomata acuminata in women: role of the male sexual partner

Hans-B. Krebs, MD, and B. Frederick Helmkamp, MD
Richmond and Falls Church, Virginia

The male sexual partners of women with genital condylomata acuminata are thought to be carriers of human papillomaviruses. It is therefore often recommended that both sexual partners be treated. We studied 360 women with genital warts to test the hypothesis that when the male partners of women with condylomata acuminata are treated, the treatment failure rate decreases. The male sexual partners of 180 of these women were examined and, if indicated, treated (treatment group). The 180 remaining male sexual partners were neither examined nor treated (control group). One hundred twenty-two (68%) men in the treatment group had human papillomavirus–associated lesions. The treatment failure rate of women was 16.7% in the treatment group and 18.9% in the control group. The difference is not statistically significant ($p > 0.05$). The results of this study do not support the hypothesis that the treatment failure rate of women with condylomata acuminata decreases if their male sexual partners are also treated. (AM J OBSTET GYNECOL 1991;165:337-40.)

Key words: Condylomata acuminata, human papillomavirus infection, human papillomavirus in men, treatment failure of condylomas

Genital condylomata acuminata are sexually transmitted and become clinically apparent 3 weeks to 8 months (average 3 months) after infection.[1] Although 65% of men have genital lesions associated with human papillomavirus (HPV) when condylomas are found on their female partners, many affected men have no symptoms and are not aware of their lesions.[2] Because penile condylomata acuminata are thought to be contagious, many physicians advocate treatment of the infected male partner to prevent reinfection of the female partner and treatment failure.[1] There is however only anecdotal evidence to suggest that women treated for condylomata acuminata have recurrences unless their male sexual partners are also treated.[3]

In this report we test the hypothesis that the control rate of genital condylomata acuminata in women is improved if their male sexual partners are also treated.

Material and methods

The study was carried out retrospectively; it included 360 women whom we examined and treated for genital condylomata acuminata. The male partners of 180 women were examined and biopsies were performed; if lesions were documented (treatment group), the men were treated. The women were matched with 180 comparable women (Table I) whose male sexual partners were neither examined nor treated (control group). Each patient claimed to have maintained a monogamous sexual relationship during the time of treatment and follow-up. Women in both groups were advised to abstain from sexual intercourse or to have their partners use condoms until follow-up examinations showed no evidence of condylomata acuminata.

Follow-up examinations of all men and women enrolled in the study included colposcopy and were carried out every 1 to 3 months for at least 1 year. The duration of follow-up for men was 12 to 29 months (mean 14.8 months); for women it was 12 to 59 months (mean 22.3 months). All treated men had their lesions eradicated with treatments previously described.[4]

All women enrolled in the study responded to therapy and were found to be without evidence of condylomas for at least 1 month during follow-up. Therefore all of them were permitted to resume sexual intercourse without condom protection. For this study treatment failure is defined as a reappearance of condylomata acuminata in a patient previously documented to be free of visible condylomata acuminata for at least 4 weeks after completion of therapy. Treatment failures detected within 6 months of completion of therapy were regarded as being early. Treatment failures detected after 6 months were regarded as being late.

Results

One hundred twenty-two (68%) of the 180 men examined had HPV-associated lesions. Fifty-six men

(46%) had condylomata acuminata; the others had papular, papillary, spiked, or flat lesions. Forty-two (34%) of the epithelial abnormalities were subclinical and could only be seen under magnification, with or without application of acetic acid. The lesions were mostly on the prepuce (71%) or penile shaft or both (54%). Lesions were less commonly found on the glans (9%), scrotum (5%), urethral meatus (5%), urethra (3%), and other areas, including thigh and anus (7%). The number of lesions ranged from 1 to >100 (median 5) and measured from <1 to 55 mm (median 3 mm) in diameter.

The time from the initiation of therapy to control of the women's lesions ranged from 1 to 272 days (mean 77.3 days) in the treatment group and from 1 to 385 days (mean 96.8 days) in the control group. The difference was not statistically significant (Student's *t* test, $p > 0.05$).

Treatment failed in 30 (16.7%) of the 180 women in the treatment group and in 34 (18.9%) of the 180 women in the control group. The difference in the treatment failure rate between the two groups was not statistically significant ($p > 0.05$, χ^2 test).

Twenty-five (83.3%) of the 30 treatment failures in the treatment group were early; five (16.7%) were late. In the control group 25 (73.5%) of the 34 treatment failures occurred early and nine (26.5%) occurred late. The difference in early and late treatment failures between the two groups of patients was not statistically significant (χ^2 test, $p > 0.05$).

Comment

In a previous study we showed that the treatment of genital condylomas in men does not decrease the treatment failure rate of cervical intraepithelial dysplasia in the female sexual partner.[5] The current study was carried out in a similar fashion in a different patient population to investigate whether examination and treatment of the male sexual partner lowers the treatment failure rate of condylomata acuminata in women. It became apparent that neither the incidence nor the time of recurrence of condylomata acuminata in women changed significantly when their male sexual partners were also examined and treated. The figures suggest that reinfection by the same male sexual partner is not an important cause of treatment failure of condylomata acuminata in women.

Reasons for treatment failure may be found in the natural history and pathophysiology of the infection. It is recognized that HPV infections involve the entire genital tract.[6,7] By contrast, manifestation of the condylomas is most often focal rather than diffuse and is probably influenced by the part of the genital tract involved, as well as by immunologic and virologic factors. The importance of cellular immunity in suppressing HPV infections is suggested by studies in persons with genetic, induced, or acquired cell-mediated immunodeficiencies. It has also been found that a subset of intraepithelial Langerhans cells, which are considered to be the first line of host defense, are locally depleted in women with HPV infections.[8] These factors may be of greater importance than reinfection with an HPV strain that patients continue to harbor in latent or subclinical form regardless of treatment attempts.[7,9] Hence, neither the treatment of the same male partner nor the use of condoms can protect from reactivation of preexisting infection. Nonetheless it is theoretically possible for a man with condylomas to pass such a high viral load to his female partner during coitus that the relative immunity of the woman with latent infection is overwhelmed and new condylomas develop. This most likely occurs when condylomata acuminata are present because these lesions contain the highest number of viruses per cell and shed the largest number of cells per contact compared with noncondylomatous lesions.[10, 11] Therefore, besides preventing HPV-associated problems in future sexual partners, treatment of exophytic condylomas in men may also be helpful to their current women partners.

It is possible that the design of the study did not permit detection of a significant difference between the two groups of patients studied. From examination of the male partners in the treatment group, it could be anticipated that approximately two thirds of the male sexual partners in the control group had HPV-associated lesions. That incidence is similar to the incidence of condylomas in men reported by other authors.[2, 12] On the basis of the findings in the treatment group, it may also be expected half of the HPV–associated genital lesions of the untreated men to be condylomata acuminata. However, many of these lesions are grossly visible and some men with condylomata acuminata may have sought medical attention, leaving relatively fewer men with exophytic lesions in the control group as compared with the treatment group. Therefore men in the control group may have been relatively less infectious than men in the treatment group.

A more perfect match of male partners could be made if all of the men were examined but only half were treated. This study design, however, would be ethically objectionable.

Another problem with the design of our study may be the recommendation that women have their male partners use condoms during intercourse as long as condylomas are present. Although all women claimed to have resumed sexual intercourse without condom protection after they were found to be free of condylomata acuminata, there was no accurate information as to the frequency of unprotected intercourse. High coital frequency with an infected person has been found to be a risk factor for HPV infection.[10]

In spite of these methodological shortcomings, this study does not support the commonly held belief that the treatment failure rate of genital condylomata acuminata in women may be lowered if the male sexual partner is also treated.

Discussion

DR. WESLEY C. FOWLER, JR., Chapel Hill, North Carolina. HPV and its related disorders, including condylomas and intraepithelial neoplasia of the female genital tract, require more and more of the physician's time, not only in attempting to treat the disorder. Also the time it takes to counsel these patients and their partners is endless. Reasonable estimates show that 25% of the women in the United States harbor HPV. It seems more and more that we know less and less about the management of HPV.

Dr. Krebs has contributed much to our knowledge of HPV-related disorders. I consider him to be a pioneer in the use of 5-fluorouracil to treat genital HPV. He addresses a question that many of us have struggled with and don't have an answer for. Should we treat the male sexual partners of women who have condylomas?

This is a retrospective study of 360 women who were examined and treated by the authors for genital condylomata acuminata. In half the women the male partners were examined and treated; in the other half no examination or treatment of the male partners was begun. Dr. Krebs's results show that there was no difference in treatment failures in the women regardless of whether their male partners were treated. Treatment failed or disease recurred in 15% to 20% of the women.

Dr. Krebs and his associate should receive an award. What a tour de force the follow-up was! Patients obviously came back religiously for Dr. Krebs to be able to pick up treatment failures only 4 weeks after patients were declared HPV free. The patients had great faith in their physicians; all 360 women were monogamous and complied with requests to use condoms or abstain from intercourse while undergoing treatment. The authors are to be commended for so greatly influencing their patients' behavior.

I have several questions for Dr. Krebs:

1. How did he select the women? Were there any exclusions because of follow-up problems? How did he find 360 women who were monogamous?

2. Were biopsies performed for all of the men? If not, could some men who had been thought to have HPV lesions not have had them, that is, did they have skin tags or benign epithelial lesions?

3. How many patients in his current study were also in his previous study?[1] How does he account for the difference in the colposcopic findings in the men in the two studies? In the 1990 study the men had more papules, and 50% required colposcopic identification. In this presentation 50% of the men had condylomas and only one third required colposcopic visualization.

4. Finally, can we say that HPV-related lesions are now so prevalent that we can no longer consider HPV to be a sexually transmitted disease?

I appreciate Dr. Krebs's sharing this information with us. I am sure these data will aid us in the management of our patients' HPV.

Dr. Krebs (Closing). In retrospective studies it is difficult to ascertain all factors, such as condom use during intercourse, sexual abstinence, and the involvement of other sexual partners, with reasonable accuracy. This information is difficult to obtain even in prospective studies. All data in the present study were obtained from patients visiting the clinic or the private office. Although many more clinic patients than private patients were treated in the past, the present study is heavily weighted in favor of private patients because of follow-up problems with clinic patients.

The high incidence of condylomata acuminata as opposed to papular or flat lesions in the male partners in this series is because the women had exophytic lesions, which are associated with HPV types 6 and 11. These HPV types also cause condylomata acuminata in men. In our previous study, we reported on women with cervical intraepithelial neoplasia. The corresponding genital lesions of this type in men are usually papular or flat because of association with HPV types other than 6 and 11.

As to the high prevalence of HPV, the question was raised as to whether HPV-associated changes in the genital area can still be regarded as a sexually transmitted disease. Although HPV has been found in approximately 25% of women who had no symptoms, the figure would probably be much higher if more sensitive probes were used for HPV detection. By using polymerase chain reactions, researchers have found HPV in 80% to 90% of sexually active women. Those figures, however, have been disputed and await further study. If they are confirmed, we need to reconsider our theories that HPV is related to genital cancer and should consider HPV to be merely a saprophyte.

Partial dissection of the zona pellucida of frozen-thawed human embryos may enhance blastocyst hatching, implantation, and pregnancy rates

Michael J. Tucker, PhD,[a] Jacques Cohen, PhD,[b] Joe B. Massey, MD,[a]
Mary P. Mayer, RNC,[a] Sharon R. Wiker, BS,[a] and Graham Wright, BSc[a]
Atlanta, Georgia, and New York, New York

The rate of successful implantation after replacement of frozen-thawed embryos in in vitro fertilization is commonly only 5% to 10% per embryo. A limiting factor may be inability of otherwise viable embryos to be released from the intact zonae pellucidae. Culture conditions and/or cryopreservation in in vitro fertilization may affect the zona and impair blastocyst hatching. Therefore opening of the zona by partial slicing by means of micromanipulation before replacement of early cleaved embryos may improve chances of eventual hatching (referred to as assisted hatching). In 65 thawed embryo replacement cycles methyl-prednisolone and antibiotics were given for 4 days mid cycle. Assisted hatching was performed in 32 cycles, with 33 cycles left as controls. Patient's age, infertility, cycle supplementation, and number of thawed and replaced embryos did not differ significantly between the two groups. Rates of viable embryonic implantation were 16% (10/63) and 9% (6/64) in the assisted hatching and control groups, respectively. Group sizes need approximately to double before this trend toward improved implantation with the use of assisted hatching reaches statistical significance. (AM J OBSTET GYNECOL 1991;165: 341-5.)

Key words: Zona pellucida, micromanipulation, cryopreservation, blastocyst hatching

The human zona pellucida, a relatively simple glycoprotein structure surrounding both the unfertilized oocyte and the early embryo, has a surprising number of biologic roles. Either these are temporally brief, such as the species-specific binding of spermatozoa to the oocyte and the subsequent block to polyspermy, or they exist over longer periods, principally as a mechanical barrier to prevent disruption of the oocyte or embryo within from immune cell attack, physical squeezing, or temporary biochemical toxicity.

Recently, certain new techniques in human in vitro fertilization and embryo transfer have highlighted the major functional aspects of the zona pellucida. Techniques to increase chances of fertilization have necessarily focused on broaching the zona pellucida to assist passage of spermatozoa[1] to or placement of spermatozoa[2] next to the oolemma. Blastomere biopsy at the embryo cleavage stage for genetic analysis[3] introduces a hole in the zona pellucida after fertilization. All of the embryos from these studies therefore have incisions in the zonae pellucidae but nonetheless have led to live births. Cohen et al.[4] have proposed that a hole in the zona pellucida may be of benefit, because it may enhance blastocyst hatching, implying that some proportion of in vitro fertilization–generated embryos actually may fail to implant for no other reason than that they are unable to shed the zonae pellucidae.

An initial study in which fresh, 2-day-old, cleavage-stage embryos underwent partial dissection of the zona pellucida before uterine transfer[5] strongly suggested that this hole in the zona improved chances of implantation. This technique (referred to as assisted hatching) has subsequently been used with cryopreserved embryos after thawing to determine if chances of implantation can be improved in such cases.

Material and methods

Sixty-five patients who had cryopreserved embryos that survived thawing before uterine replacement were considered for this study. Thirty-three patients were allocated on an alternating basis to the control group (embryos left with intact zonae pellucidae), and 32 were assigned to the experimental assisted hatching group. Embryos were originally generated from ovarian stimulation protocols, as previously described,[6] with the majority in both the control and assisted hatching groups from cycles stimulated with a combination of clomiphene citrate (Serophene; Serono, Norwell, Mass.) and human menopausal gonadotropin (Pergonal, Serono).

All embryos had been cryopreserved at between the

zygote (one-cell) stage and the six-cell stage in 1.5 mol/L 1,2-propanediol and 0.1 mol/L sucrose, and then they were stored in 0.75 ml glass ampules.[6] This process was relatively rapid, with embryos being taken directly from 37° C culture into 1.5 mol/L 1,2-propanediol at room temperature for 10 minutes; this was followed by transfer into 1,2-propanediol plus 0.1 mol/L sucrose. Embryos were then immediately placed individually into indelibly marked glass ampules that were heat sealed before introduction into a programmable liquid nitrogen freezer. From room temperature embryos were cooled at a rate of −2° C/min to −6.5° C, at which temperature they were held for 15 minutes. After 5 minutes' holding time, the ampules were manually seeded with chilled forceps. Finally, embryos were cooled at a rate of −0.3° C/min to −36° C and plunged into liquid nitrogen ready for storage. Thawing was performed rapidly in a 31° C water bath, followed by washing at room temperature through a series of 1,2-propanediol dilutions in 0.2 mol/L sucrose. A final six washes were carried out in fresh culture medium before culture at 37° C. Thawed zygotes were cultured for up to 24 hours to observe cleavage, and cleavage-stage embryos, when thawed, were left for a minimum of 2 hours in culture to check viability. All culture was carried out in sodium bicarbonate–buffered Earle's balanced salt solution, supplemented with 15% maternal serum or from screened donor serum.

All patients received a combination of 16 mg methylprednisolone (Medrol, The Upjohn Co., Kalamazoo, Mich.) daily, plus 250 mg tetracycline (Barr Laboratories, Pamona, N.Y.) four times daily from the day of estimated ovulation for 4 days, to prevent possible leukocytic invasion of the early embryo through the hole in its zona pellucida. No harmful side effects arose in any of these patients or in previous studies where this medication had been used in this fashion.[7] All patients were ovulatory; however, in some cases 50 mg clomiphene citrate was administered daily from day 5 to day 9 to regularize ovulation[8] in 16 patients in the assisted hatching group and 20 in the control group. Ovulation was assessed in all cases by urinary luteinizing hormone (LH) assay (LH MAIAclone, Serono) to monitor the endogenous LH surge. Two patients in the control group and one in the assisted hatching group received an additional 3000 U human chorionic gonadotropin (hCG) (Profasi, Serono) to initiate ovulation, because no endogenous LH surge occurred. Thawing was scheduled according to embryonic age with necessary adjustments made to accommodate embryonic-endometrial asynchrony.[8] Essentially, mock oocyte collection was assessed as occurring 25 hours after an LH surge. The age of the embryo was then added; this was determined to be the time elapsed between original oocyte collection and time of freezing, regardless of the time of insemination, although >90% of inseminations occurred between 3 and 6 hours after oocyte retrieval. In the case of zygotes thawing was performed 6 to 9 hours in advance of embryonic-endometrial synchrony. For cleaved embryos thawing was performed even earlier at 9 to 12 hours before synchrony. The "early" thawing of embryos compensates for two factors: first, a marginal slowing of embryonic development in vitro can be accommodated; second, the thawed embryo also requires some time to recover metabolically.

Within 2 hours before replacement all embryos in

the assisted hatching group underwent partial dissection of the zona pellucida with fine, pulled glass pipettes and needles that were mounted on an inverted microscope with Nomarski interference optics and equipped with micromanipulators and an electrically heated stage. This procedure was carried out in a warm glass well slide with the embryo in a droplet of medium under mineral oil. The technique is identical to that described for partial zona dissection of unfertilized oocytes,[9] except there was no need to remove cumulus cells with hyaluronidase, and the embryo was not exposed to sucrose to shrink it and so increase the perivitelline space. All embryo replacements were performed as atraumatically as possible with the Wallace embryo replacement catheter (H.G. Wallace, Colchester, United Kingdom). Initial assays for β-hCG were carried out at 12 to 14 days after embryo replacement, with repeats at 3 to 7 days if positive, until an ultrasonographic scan was performed at approximately 7 weeks of pregnancy.

Results

Ages of patients were not significantly different between the control and assisted hatching (Table I), and no infertility type predominated significantly between the groups.

Marginally more pronucleate (one-cell) embryos were frozen and thawed in the assisted hatching group (49.4% vs 41.7%), with more cleavage-stage embryos being frozen and thawed in the control group (Table II). This fact accounted for the slightly better partial embryonic survival rate in the assisted hatching group (25% vs 30.7%), because zygote thawing success is an all-or-nothing event. Consequently, overall survival in the assisted hatching group is fractionally less (76.9% vs 77.7%). Nevertheless, very similar numbers of embryos were both thawed and replaced in both groups.

The comparison of pregnancy outcomes in these frozen-thawed embryos indicates a definite trend toward better viable implantation after application of the assisted hatching procedure (Table III). Because of the limited number of patients available for this study, the results have yet to reach statistical significance.

Comment

As appears to be the case with fresh embryos, a relatively small incision in the zona pellucida is not incompatible with development and implantation of frozen-thawed human embryos. In fact, these preliminary results even suggest that such a hole in the zona pellucida may improve chances of implantation, presumably through enhanced chances of hatching of the blastocyst. Malter and Cohen[10] showed that human and mouse embryos arising from oocytes fertilized by means of partial zona dissection hatched more frequently and at an earlier time than embryos with fully intact zonae. As an extension of this observation, it has been consistently noted that the viable embryonic implantation rate of embryos from fertilized oocytes after partial zona dissection in cases of male factor infertility is higher than that of conventionally fertilized oocytes.[5]

One of the few morphologic factors that significantly correlates with embryonic viability is the presence of thin patches in the zona pellucida of both fresh and frozen-thawed human embryos.[11] That this thinning of the zona is an active process, integral to the embryo itself, was noted by Wright et al.,[12] when the zonae of some 28% of in vitro cultured human zygotes were seen to become thinner during the period before uterine replacement at the cleavage stage. It is also possible that lysins within the female reproductive tract assist in the dissolution of the zona pellucida, a notion supported by the increased incidence of blastocyst hatching seen with human embryos cocultured with uterine cells.[13] However, this effect also could be due to the more expanded nature of cocultured embryos as they apply greater physical pressure to the surrounding zona pellucida.

It is known that in vitro culture causes "spontaneous" hardening of the zona pellucida in the mouse.[14] In the context of thawed embryo development, an additional factor may have some bearing on the benefit of assisted hatching for cryopreserved embryos. If we accept that there may be some change in the physical nature of the zona pellucida as a result of the cryopreservation procedure, a change that makes the zona more brittle and resilient to hatching, then dissection of the zona should ameliorate this to allow the blastocyst to release itself more easily at the time of hatching in utero. The zona of the unfertilized oocyte after cryopreservation is thought to differ markedly from that of the fresh oocyte, as seen in the lowered spermatozoal penetration of thawed oocytes.[15] Indeed, comparison of the mechanics of the zona dissection technique in both fresh and frozen-thawed embryos gives the impression that the fresh zona is considerably more malleable. Biochemical characterization of any such changes of the zona before and after cryopreservation needs to be established.

Cohen et al.[7] have discussed at length the means by which midcycle corticosteroids and antibiotics may protect zona-dissected preimplantation embryos. This work cited a small study of embryo transfer of partial zona dissection embryos, with and without corticosteroids and antibiotics, in which implantation was considerably improved in the group with midcycle supplementation. A more extensive study of the midcycle use of antibiotics and corticosteroids in a randomized fashion among all of our patients undergoing in vitro fertilization and embryo transfer has shown no intrinsic benefit for implantation with this supplementation regimen (unpublished observations). In this study all patients received this midcycle supplementation, and it is assumed that any enhancement of implantation is independent of the midcycle antibiotics and corticosteroids.

Assisted hatching has yet to prove significantly advantageous in the small group of patients so far considered. Numbers in this study need to be approximately doubled if the trend is to reach statistical significance. One obvious reservation of this study is that any extra handling of human embryos, in the form of micromanipulative zona dissection, may be potentially hazardous. However, while zona dissection proves not to be detrimental when compared with control, unmanipulated embryos, there seems every reason to continue this study to establish whether assisted hatching is truly beneficial to pregnancy outcome after embryo cryopreservation.

We thank Drs. Carlene Elsner, Hilton Kort, Dorothy Mitchell-Leef, and Andrew Toledo whose clinical skills also contributed to this work.

Discussion

DR. ANIBAL A. ACOSTA, Norfolk, Virginia. This article reviews the application of partial zona pellucida dissection to cryopreserved-thawed human preembryos and its effects on the implantation rate and pregnancy outcome. In general, the implantation rate is defined as the number of gestational sacs identified in relation to the number of preembryos transferred. The authors have considered only viable implantations (heartbeats present).

The changes induced to the zonae pellucidae of the preembryos after cryopreservation have not, to my knowledge, been elucidated. The very scanty information available refers to mouse oocytes cryopreserved at 4° C with a different procedure than the one used for human preembryo cryopreservation. A lower fertilization rate was observed,[1] probably because of induced zona reaction during either freezing or thawing. Zona drilling overcomes the problems, thereby indicating that the block of fertilization is at the level of the zona in the mouse system.[2]

There are clear indications in the literature that preembryos that are allowed to continue their development in vitro have a high degree of developmental arrest; only 30% reach the stage of expansive blastocyst and then hatch.[3] Therefore, at least under in vitro culture conditions, a significant amount of preembryos do not achieve a stage at which implantation can occur.

The field of assisted fertilization has introduced several different techniques of micromanipulation to try to overcome the problem of lack of fertilization. The results are so dismal, mainly if authentically poor-quality sperm is used, that its clinical usefulness in the foreseeable future is, to say the least, doubtful. Nevertheless, micromanipulation for the purpose of assisted hatching seems to have a more credible role in assisted reproduction.

Our implantation rate in Norfolk, Virginia, for fresh preembryos transferred for the years 1989 and 1990 was 11.2%.

The authors administered 50 mg clomiphene citrate to 16 of the 32 patients allocated to the assisted hatching group (50%) and to 20 of 33 patients in the control group (60.6%). Although in some studies[4] there seems to be no difference in the implantation rate of cryopreserved zygotes and preembryos when 50 mg clomiphene citrate was used, as in this investigation, a substantial part of controversial literature seems to indicate a possible deleterious effect of clomiphene citrate on endometrial morphologic characteristics, synchrony, development, receptor content, and pregnancy rates.[5-7] Therefore, in a study in which the end points are the preembryo implantation rate and pregnancy outcome, it will be safer, in terms of experimental design, to stay away from that treatment.

The number of preembryos cryopreserved and transferred in each one of the stages between zygote and six cells in the control and study group is not given, so we should assume that the distribution was even in both groups.

Other information that would be useful to have is the timing of the transfer during the natural cycle and the embryo survival rate after cryopreservation, which may be important to judge the embryo quality obtained with the protocol used for stimulation. Morphologic evaluation of the embryo quality in both groups would be another useful criterion.

The protocol for monitoring these patients and the time of ultrasonographic examination after a positive pregnancy test result would be other information of interest to the reader. Perhaps all these questions can be addressed by the authors.

The implantation rates, with only sacs with fetal heartbeats used as a reference point, are 9% and 16% in the control and study groups, respectively. As the authors stated, these numbers represent only a trend without actual statistical significance. The term-ongoing pregnancy rate per transfer in the control group is somewhat low by the present standards.

Just as a point of reference, the Norfolk preembryo cryopreservation program from April 1987 (time of inception) through December 1990 showed a 64.0% survival rate of both, out of the total number of preembryos thawed and out of the preovulatory oocyte–derived preembryos thawed. The implantation rate was 11.4% without artificial hatching.

I think this line of research should continue until we can demonstrate clearly whether zona hatching can improve the implantation and pregnancy rate of cryopreserved preembryos.

Dr. Massey (Closing). The patients who received clomiphene were selected according to clinical criteria. Our survival of embryos is associated with about a 40% loss of embryos from the cryopreservation process. Our implantation rate per frozen embryo replaced is about 9%, as in the group that we reported. It is a good point that we should have made morphologic observations comparing the two groups of patients and relating them to survival and pregnancy rates. It is hoped that a year from now we will see real progress in this field.

Clinical Opinion

Polycystic ovary syndrome and the androgen-insulin connection

Shahla Nader, MD
Houston, Texas

The association of hyperandrogenism, insulin resistance, and polycystic ovarian disease is well established. The accompanying hyperinsulinemia results in acanthosis nigricans, an epiphenomenon of this syndrome. The knowledge that states of insulin resistance of diverse causes are associated with ovarian hyperandrogenism makes the argument for insulin-driven ovarian androgen secretion compelling. However, equally compelling evidence suggests that hyperandrogenism may contribute to insulin resistance and hyperinsulinemia. The irreconcilable differences between these two hypotheses have resulted in an array of contradictory studies. In this article a unified concept of polycystic ovary syndrome and its androgen-insulin connection is proposed. The hypothesis incorporates the role of hyperinsulinemia in the androgen excess observed (and vice versa); the key to this connection is the androgen-dependent change in regional body fat distribution and its metabolic consequence. The pathophysiologic features of polycystic ovary syndrome, which has important clinical sequelae, deserve further consideration. (AM J OBSTET GYNECOL 1991;165:346-8.)

Key words: Polycystic ovary syndrome, hyperandrogenism, insulin resistance, acanthosis nigricans

Since the original correlation of diabetes and hirsutism in the early 1920s, numerous studies and investigators have confirmed the association of hyperandrogenism and insulin resistance. In a landmark article Kahn et al.[1] reported on six patients with insulin resistance and acanthosis nigricans (which is an epiphenomenon of hyperinsulinemia) in whom insulin-binding studies demonstrated two abnormalities, namely, receptor abnormalities (type A) and anti-insulin-receptor antibodies (type B), the latter of which is associated with immunologic disease. Both syndromes have been associated with hyperandrogenism. In a subsequent study[2] a third variety of insulin resistance (type C), hyperandrogenism, and acanthosis nigricans were documented in obese women. Subjects in the type C syndrome lacked insulin receptor antibodies, and in these women (unlike the individuals with the type A syndrome) insulin binding to monocytes increased after short-term and long-term caloric restriction; thus the obesity of type C subjects was thought to be the mediator of insulin resistance.

Recognition of the remarkable association of hyperandrogenism with the hyperinsulinemia of these varied syndromes of insulin resistance led to the hypothesis that insulin may mediate ovarian androgen synthesis. Dunaif et al.[3] and Stuart et al.[4] demonstrated that insulin infusions to hyperandrogenic women produced a short-term increase in androstenedione. In a study that used glucose to stimulate further insulin production, Smith et al.[5] demonstrated a rise in androstenedione, testosterone, and dihydrotestosterone in hyperandrogenic women with insulin resistance. In addition, the magnitude of the rise in these androgens correlated strongly with the cumulative insulin response to the glucose challenge.

Both insulin and insulin-like growth factor-I receptors have been identified in human ovarian cells.[6] Barbieri et al.[7] studied the effect of insulin on incubated ovarian stromal fragments from patients with hyperandrogenism and found that insulin increased accumulation of testosterone and androstenedione. Thus in vivo and in vitro studies have confirmed that, in the presence of gonadotropins, insulin may induce ovarian androgen synthesis, either through the activation of its own receptors or via insulin-like growth factor-I receptors (the so-called receptor spillover phenomenon).[8]

In spite of such rationalization and the convincing nature of the data, there is an equally strong body of

evidence that suggests a role for hyperandrogenism in the genesis of insulin resistance. For example, there are documented cases of luteomas and diabetes in which diabetes resolved after removal of the androgen-producing tumor.[9] Treatment of aplastic anemia with testosterone derivatives may result in glucose intolerance,[10] and in a recent case even danocrine (a modified androgen used to treat endometriosis) induced a temporary diabetic state.[11] Conversely, spironolactone (an antiandrogen) has been shown to lower insulin concentrations in women with polycystic ovary syndrome.[12]

Where is the connection?

It is not disputed that hyperandrogenism and hyperinsulinemia are linked, but where is the connection? Does hyperinsulinemia cause hyperandrogenism, or does hyperandrogenism induce a state of insulin resistance and subsequent hyperinsulinemia? Is there a missing link?

The missing link

In an excellent account of the biologic characteristics of regional fat distribution, Kissebah and Peiris[13] reviewed the information pertaining to regional body fat distribution. A summary of their data and the existing literature allows the following conclusions: (1) Obesity in women may be qualified according to its pattern of distribution: The more "android" the obesity (abdominal-visceral fat deposition), the greater the waist-to-hip ratio. "Gynoid" obesity is associated with femoral-gluteal fat deposition and a low waist-to-hip ratio. (2) Android obesity is, as its name implies, associated with "maleness." In a study of premenopausal women those with higher waist-to-hip ratio had a higher percent of free testosterone and lower sex hormone–binding concentrations.[14] In keeping with that observation, androgens have been shown to mediate the deposition of fat into abdominal-visceral depots (versus the femoral-gluteal region). For example, female-to-male transsexuals who are given testosterone accumulate fat in abdominal-visceral depots.[15] (3) Epidemiologically, Android obesity is linked to non-insulin-dependent diabetes mellitus.[16] (4) Morphologically and metabolically, fat cells in abdominal-visceral fat depots are distinct from femoral-gluteal fat cells. Whereas the femoral-gluteal depot is primarily a storage organ for female stresses such as pregnancy and lactation, the abdominal-visceral depot is a storage of energy reserves that can be easily and rapidly mobilized.[17] For example, abdominal-visceral fat cells exhibit higher rates of basal and catecholamine-induced lipolysis that results in greater free fatty acid concentrations.[18] (5) Androgens may mediate metabolic abnormalities via two additive mechanisms. First, androgens may directly impair hepatic and peripheral insulin action.[19] Second, by encouraging the deposition of abdominal-visceral fat with its resultant increase in free fatty acid flux, androgens impair hepatic insulin extraction and hepatic and peripheral insulin sensitivity.[20] These factors result in excess circulating insulin concentrations. Thus android obesity, which is a consequence of hyperandrogenism, leads to a state of insulin resistance and hyperinsulinemia that is independent of and additive to that of the degree of overweight.

The androgen-insulin connection: A unified concept

I propose that the following model provides a unified concept of the androgen-insulin connection (Fig. 1). Hyperinsulinemia, regardless of its cause and in the presence of permissive concentrations of gonadotropins, stimulates the ovarian thecal stromal compartments to produce androgens. These androgens not only directly influence insulin action but also increase the recruitment and size of abdominal adipocytes, which, through their specific metabolic qualities, lead to a further state of insulin resistance and hyperinsulinemia that is independent of the degree of overweight (i.e., via the high free fatty acid milieu suggested by Kissebah and Peiris[13]). This model can explain everything we know about polycystic ovary syndrome and its androgen-insulin connection. It explains how states of insulin resistance and hyperinsulinemia of diverse causes can be associated with hyperandrogenism (Fig. 1, 1). It explains how lowering gonadotropins (e.g., with the use of gonadotropin-releasing hormone analogs) may lower androgens (Fig. 1, 2) without necessarily altering insulin resistance (for example, it would not be expected to affect anti-receptor-antibody–mediated insulin resistance).[21, 22] It explains the commonly observed association between polycystic ovary syndrome and android obesity (Fig. 1, 3), and finally it explains how, under some circumstances, lowering androgen levels may indeed improve insulin sensitivity (Fig. 1, 4).

Ultrasonographic screening for the Down syndrome fetus

Charles J. Lockwood, MD, Lauren Lynch, MD, and Richard L. Berkowitz, MD
New York, New York

The usefulness of ultrasonography in detecting fetuses with Down syndrome in the second trimester has been the subject of considerable debate during the past 3 years. Conflicting reports have led to increasing confusion about the subject in the medical community and among the public. A review of the existing literature indicates that structural malformations that are chiefly cardiac are present in half of Down syndrome fetuses but are not consistently found during routine second-trimester ultrasonography. Although excess posterior nuchal skin-fold thickness is frequently present in infants with Down syndrome, it is also not consistently identified during second-trimester ultrasonographic examinations. Studies evaluating the efficacy of screening programs that are based on femur length shortening associated with Down syndrome have revealed markedly discrepant intercenter results. Although variations in methods may account for some of the observed variability, the magnitude of femoral shortening in Down syndrome suggests that this measurement may be only marginally useful. In summary, antenatal ultrasonography will allow for the detection of only those fetuses with Down syndrome who have multiple characteristic phenotypic features or anomalies. Moreover, current second-trimester ultrasonography does not appear to be either sensitive enough or specific enough to be used as a unique Down syndrome screening modality; however, it may be a useful adjunct to maternal age and serum biochemical markers in the assignment of risk for Down syndrome. (Am J Obstet Gynecol 1991;165:349-52.)

Key words: Ultrasonography, Down syndrome, screening

The incidence of Down syndrome is approximately 1 in 1000 live births.[1] This incidence is expected to increase modestly over the next 10 years as the number of women between 35 and 49 years of age increases.[2] However, the infants of women older than 34 will still account for only 8.6% of all live births and 39% of Down syndrome cases by the year 2000. Thus even a fully used Down syndrome screening program that is based on maternal age will fail to identify 61% of Down syndrome cases.[2]

The association of decreased maternal serum α-fetoprotein levels with fetal Down syndrome has now been well established. Risk determination that is based on a combination of maternal serum α-fetoprotein value and maternal age allows the detection of up to one-third of fetuses with Down syndrome and necessitates karyotype analysis in 5% of pregnant patients younger than 35.[3] However, Down syndrome risk assignment paradigms that use maternal age with a combination of maternal serum α-fetoprotein, human chorionic gonadotropin, and estriol values may identify 60% of fetuses with Down syndrome and necessitate karyotype analysis in only 5% of pregnant women.[4]

As a result of the explosive increase in the number of women who are undergoing diagnostic antenatal ultrasonographic studies, it was logical that ultrasonography also be evaluated in the quest for improved detection rates of Down syndrome. Unfortunately, initial reports have provided contradictory results and inconsistent methodologic approaches. An examination of the published experience of those who have used ultrasonographic indicators to detect fetuses with Down syndrome and speculations about the usefulness of this approach are the subjects of this review.

Why screen for fetal Down syndrome with ultrasonography?

Because most pregnant women now routinely undergo ultrasonographic evaluation in the second trimester, failure to use ultrasonographic information that could alter risk assignment of Down syndrome at the time of those examinations would be injudicious. However, this argument for the use of ultrasonographically derived data to determine the risk of Down syndrome requires that such data be reliably obtained, be effective in discriminating between fetuses with Down syndrome and unaffected fetuses, and be obtainable at a gestational age that is early enough to be useful clinically.

Ultrasonographic detection of Down syndrome fetus: Identification of coexistent anomalies

Certain malformations have been specifically associated with fetal Down syndrome. For example, 30% of

fetuses with duodenal atresia have Down syndrome,[5] but only 3% to 8% of fetuses with Down syndrome have detectable upper gastrointestinal tract obstructions. Moreover, although the ultrasonographic diagnosis of duodenal atresia is readily made after 28 weeks' gestation, its consistent diagnosis may be difficult or impossible before 24 weeks.[5] Thus duodenal atresia, which is suggestive of Down syndrome, is not a useful ultrasonographic marker for most cases of Down syndrome.

The prevalence of aneuploidy in fetuses diagnosed with congenital heart defects has been reported to be 32%.[6] However, the vast majority of these fetuses have the far less prevalent trisomy 18 or trisomy 13.[6] This may reflect selection bias as a result of the more severe anatomic anomalies associated with fetuses with trisomy 18 or trisomy 13. The prevalence of congenital heart defects in fetuses with Down syndrome is generally accepted to be 40% to 50%; an atrioventricular canal defect is considered the "signature" cardiac lesion. However, although an atrioventricular canal defect is detectable on targeted four-chamber views of the heart, this lesion accounts for a minority of congenital heart defects that are associated with Down syndrome. Atrial and ventricular septal defects are more common and are not easily identified, even on targeted four-chamber views of the fetal heart. Thus, except in centers with advanced fetal echocardiography facilities, fetal congenital heart defects do not appear to be practical ultrasonographic markers for Down syndrome.

Renal anomalies are more common in aneuploid fetuses than in unaffected fetuses, but most fetuses with Down syndrome do not have major genitourinary tract anomalies. Benacerraf et al.[8] have recently described an association between mild fetal pyelectasis and fetal Down syndrome. They noted mild pyelectasis in 3.3% of unaffected fetuses compared with 25% of fetuses with Down syndrome. The usefulness of this observation is uncertain, because the prevalence of renal pelviceal dilatation in unaffected fetuses has been reported to be as high as 23%.[8]

Other malformations rarely associated with fetal Down syndrome include cystic hygromas, pleural effusions, and omphaloceles. Hygromas detected in utero are almost never accompanied by Down syndrome,[9] and the lesion is also extremely uncommon in fetuses with Down syndrome. Omphaloceles are associated with chromosomal abnormalities in 15% of cases, but only 12% of these are Down syndrome.[5] Furthermore, omphaloceles are rare in infants with Down syndrome. Pleural effusions, with or without hydrops, have been associated with Down syndrome,[10] but again infants with Down syndrome rarely have this abnormality.

In summary, screening for congenital malformations would result in a low detection rate for fetuses with Down syndrome because of the relative rarity of readily diagnosable coexistent malformations.

Ultrasonographic detection of Down syndrome fetus: Identification of typical phenotypic features

The phenotypic features of the infant with Down syndrome are sufficiently characteristic to have permitted the clinical diagnosis of Down syndrome in the prekaryotype era. Three of these features lend themselves to possible detection via ultrasonography: excess posterior nuchal skin-fold thickness, dysplasia of the midphalangeal ossification center of the fifth finger, and shortened length of long bones.

Excess nuchal skin-fold thickness. Benacerraf et al.[11] first described the association of ultrasonographically detected excess (≥ 6 mm) posterior nuchal skin-fold thickness with fetal Down syndrome. This sign was reported to be present in 9 of 21 fetuses with Down syndrome (43%) between 15 and 20 weeks' gestation but in $<0.1\%$ of unaffected pregnancies.[11] However, the reproducibility of this sign has been questioned.[12]

The efficacy of nuchal skin-fold thickness determinations in detecting the fetus with Down syndrome has also been assessed by several other investigators. Perrella et al.[13] identified excess nuchal skin-fold thickness in only 21% (3/14) of fetuses with Down syndrome, a false-positive rate of 9%. Hill et al.[14] observed excess nuchal skin-fold thickness in 9% (2/22) of fetuses with Down syndrome but did not report their false-positive rate. In contrast, Lynch et al.[15] identified excess nuchal skin-fold thickness in five of nine fetuses with Down syndrome (55%) but in none of their unaffected dizygotic twin controls.

The effect of gestational age on the extent of nuchal thickening has not been adequately evaluated. Therefore there is a need for autopsy confirmation of the prevalence of excess nuchal skin-fold thickness in second-trimester fetuses with Down syndrome. Toi et al.[12] evaluated 13 autopsy reports of abortuses with Down syndrome and reported an 18% prevalence of excess nuchal skin-fold thickness. However, the neck was not described in three cases and was described as being "normal" in six cases.

Clinodactyly and hypoplasia of midphalanx of fifth finger. Down syndrome is associated with a characteristic hypoplasia or dysplasia of the midphalanx of the fifth finger in 60% of infants; there is resultant curvature (clinodactyly) in 50%.[16] Benacerraf et al.[16] observed hypoplasia of the midphalangeal ossification center with concomitant clinodactyly of the fifth finger in three of four fetuses with Down syndrome between 17 and 20 weeks' gestation. In a subsequent study the same group compared the ratio of fifth digit/fourth digit midphalangeal ossification center lengths in 1024 normal fetuses and in 8 fetuses with Down syndrome. The mean ratios were 0.85 and 0.59, respectively. A ratio of ≤ 0.7 identified 6 of 8 fetuses with Down syn-

B/F, Ratio of biparietal diameter to femur length; *SD*, standard deviation; *M/E FL*, ratio of measured femur length to expected femur length for a given biparietal diameter.

*Based on prevalence of Down syndrome of 1 in 710 at 16 weeks.

drome; the false-positive rate was 18%. Postmortem confirmation of these prevalence data is not yet available. Moreover, given the technical expertise and state-of-the-art equipment required to make measurements (1 to 4 mm) that approach or exceed the lateral resolution of many ultrasonographic machines, this approach is unlikely to have immediate widespread application.

Biometric differences in long-bone lengths between Down syndrome fetuses and unaffected fetuses. Lockwood et al.[18] suggested the use of routine biometry measurements in the ultrasonographic identification of fetuses at risk for Down syndrome. They retrospectively analyzed ultrasonographically derived biometry differences in fetuses with Down syndrome and in unaffected control fetuses between 15 and 23 weeks' gestation. No statistically significant differences were noted in the cephalic index or biparietal diameter between the groups at any gestational age. However, a significant degree of femur length shortening in affected fetuses was noted. Moreover, the best discriminator of the fetus with Down syndrome was the ratio of biparietal diameter to femur length. When a cutoff value of 1.5 SD above the unaffected population biparietal diameter/femur length mean is considered, at least 50% of fetuses with Down syndrome could be identified in 6% of the total population.

Benacerraf et al.[19] evaluated femur length as a function of biparietal diameter in fetuses with Down syndrome versus control fetuses. They used a ratio of the measured femur length to expected femur length for a given biparietal diameter. With a measured femur length/expected femur length cutoff of 0.91, they identified 68% of fetuses with Down syndrome (false-positive rate 2%). Subsequent published reports have used either the biparietal diameter/femur length at a given gestational age or the measured femur length/expected femur length for a given biparietal diameter. Their findings have been highly variable (Table I).

The explanation for such different results is unclear. Small numbers of Down syndrome and control fetuses, as well as differences among manufacturers of ultrasonographic equipment, models, and transducers, are present. Operator experience and measurement technique may also vary significantly among centers. Furthermore, longer ascertainment periods for Down syndrome cases compared with control populations appear to be the rule. This latter bias could result in less operator experience, inferior ultrasonographic equipment, and reduced ultrasonographic resolution for the earlier Down syndrome cases compared with controls at some of the centers.

Biologic differences in long-bone lengths between fetuses with Down syndrome and unaffected fetuses may not be of sufficient magnitude to permit discrimination by ultrasonography in the second trimester, as a result of the limits of lateral resolution in the equipment available at this time. FitzSimmons et al.[20] have assessed postmortem fetal long-bone lengths, either directly or with radiographic studies, in fetuses with Down syndrome and in unaffected fetuses. They found small but significant differences between the femur lengths of Down syndrome fetuses and those of unaffected fetuses. However, a ratio of measured femur length to expected femur length of <0.91 permitted the detection of only 16% of Down syndrome abortuses in their study. The authors did not indicate this ratio's false-positive rate or whether alternate cutoff ratios improved sensitivity.

Interestingly, FitzSimmons et al. found that upper-extremity long-bone lengths were more severely affected than lower-extremity lengths in fetuses with Down syndrome. They found that approximately 30% of abortuses with Down syndrome had humeral lengths <2 SD below the mean of those that were unaffected. This suggests that humeral length may be a better discriminator of fetal Down syndrome than femur length.

Comment

The utility of ultrasonographic Down syndrome detection schemes should be judged by whether the pertinent ultrasonographic markers are reliably obtained and by whether they efficiently discriminate between fetuses with Down syndrome and euploid fetuses at a gestational age early enough to be clinically useful. Unfortunately, none of the currently proposed approaches satisfactorily fulfills all these requirements. Screening for characteristic congenital malformations would result in a low detection rate of Down syndrome, and many of these cases would be identified only after 24 weeks' gestation. Second-trimester ultrasonographic identification of typical Down syndrome phenotypic features is hindered by the subtlety of the findings, which mandate significant technical expertise. Furthermore, there is considerable overlap of these features with the unaffected population, and the effects of gestational age exacerbate this overlap.

Second trimester ultrasonography does not as yet appear to have a useful primary role in Down syndrome screening. We believe, however, that fetal biometry and assessment of nuchal skin-fold thickness may (particularly if measurements of the upper extremity are included) be an adjunct to maternal age, maternal serum α-fetoprotein, and human chorionic gonadotropin values in the assignment of risk for Down syndrome.

The fetal-pelvic index: A method of identifying fetal-pelvic disproportion in women attempting vaginal birth after previous cesarean delivery

Gary R. Thurnau, MD, David H. Scates, MD, and Mark A. Morgan, MD
Oklahoma City, Oklahoma

In 1986 the fetal-pelvic index was introduced as an accurate method of prospectively identifying the presence or absence of fetal-pelvic disproportion. The concept of the fetal-pelvic index is one in which the fetal head and abdominal circumferences (ultrasonographic mensuration) are compared with the respective maternal pelvic inlet and midpelvic circumferences (x-ray pelvimetry). The purpose of this study is to evaluate the efficacy of this index as a predictor of fetal-pelvic disproportion in gravid women attempting vaginal birth after previous cesarean delivery. Findings of the fetal-pelvic index are compared with those of two other means of identifying fetal-pelvic disproportion (Colcher-Sussman x-ray pelvimetry and ultrasonographically derived estimated fetal weight of ≥4000 gm). Of the 65 prospective study participants, 18 (28%) failed to progress in labor, and a repeat cesarean delivery was required. Forty-seven of the 52 patients with a negative fetal-pelvic index value were delivered vaginally (negative predictability = 0.90). Of the five with false-negative fetal-pelvic index values, four fetuses persisted in an occipitoposterior position and failed to progress in labor. All 13 patients with a positive fetal-pelvic index value failed to progress in labor and required a cesarean delivery (positive predictability = 1.00). In contrast, when used alone, neither x-ray pelvimetry nor ultrasonography-determined estimated fetal weight of ≥4000 gm provided accurate identification of fetal-pelvic disproportion. (AM J OBSTET GYNECOL 1991;165:353-8.)

Key words: Fetal-pelvic disproportion, fetal-pelvic index, vaginal birth after previous cesarean delivery

Since 1970 the dramatic increase in the rate of cesarean section has made it the most frequently performed major operation in the United States.[1-3] Furthermore, *elective repeat cesarean* has become the most common indication for cesarean delivery.[4, 5] Although the safety of vaginal birth after previous cesarean delivery has been well documented,[6-10] elective repeat cesarean remains the rule in most labor and delivery units.

Flamm et al.[11] reported on the frequency of vaginal birth after previous cesarean delivery and found it to be related to the indication for the prior cesarean delivery. In their multicenter study of 1776 labor trials, women with failure to progress or cephalopelvic disproportion as the documented indication for cesarean delivery had the lowest success rate (65%) for subsequent vaginal birth whereas those women with breech presentation as the indication had the highest success rate (88%). Although approximately 75% of women attempting vaginal birth after cesarean delivery reportedly are successful,[11] a method of prospectively identifying fetal-pelvic disproportion could prevent prolonged unsuccessful labor trials in the majority of women destined to fail the attempt.

In 1986 the fetal-pelvic index was introduced as an accurate method of prospectively identifying the presence or absence of fetal-pelvic disproportion.[12] The concept of the fetal-pelvic index is one in which the fetal head and abdominal circumferences (passenger) are compared with the respective maternal pelvic inlet and midpelvic circumferences (passage). The purpose of this study is to evaluate the accuracy of the fetal-pelvic index as a predictor of fetal-pelvic disproportion and delivery outcome in gravid women attempting vaginal birth after previous cesarean delivery. Results of the fetal-pelvic index data are compared with those of two other means of identifying fetal-pelvic disproportion (Colcher-Sussman x-ray pelvimetry[13] and ultra-

sonographically determined estimated fetal weight of ≥4000 gm).[14]

Material and methods

Seventy-four gravid women between 35 and 43 weeks' gestation with a desire for vaginal birth after previous cesarean delivery, were entered into the study between Nov. 1, 1988, and Jan. 31, 1990. Nine women were excluded. Of these nine, five did not have x-ray pelvimetry performed, two did not have fetal ultrasonographic measurements performed, and two had an inadequate labor trial before cesarean delivery (cervical dilatation <5 cm). Of the 65 study participants, 64 fetuses presented in cephalic position, and one was a frank breech presentation. Spontaneous labor was observed in 58 women, and seven received intravenous oxytocin-stimulated labor (five inductions, two augmentations). All patients were monitored with a fetal scalp electrode and an intrauterine pressure catheter.

An adequate labor trial was defined as (1) uterine contractions of at least 40 mm Hg in intensity and 60 seconds in duration, (2) a frequency of at least three contractions in 10 minutes, and (3) cervical dilatation of ≥5 cm for a minimum of 2 hours.

Fetal ultrasonographic evaluations were performed in the labor rooms, by means of a portable ADR 4000 S/L linear-array scanner with a 3.5 MHz transducer calibrated to a sound velocity in soft tissue of 1540 m/sec (Advanced Technology Labs Inc., Tempe, Ariz.). Diameters of the fetal head—outer-to-inner biparietal, outer-to-outer transverse, and outer-to-outer anterior-posterior—were determined by built-in electronic calipers applied to a freeze-frame image of the plane that included the thalamus, the septum cavum pellucidum, and a symmetrically aligned midline echo. Fetal abdominal diameters were also determined from a freeze-frame image that visualized the plane perpendicular to the fetal spine at the level of the portal vein bifurcation and stomach. By means of electronic calipers the anterior-posterior diameter was measured from the outer aspect of the fetal spine to the outer anterior abdominal wall. The outer-to-outer transverse diameter was measured 90 degrees to the anterior-posterior diameter.

With regard to the maternal pelvic measurements, respective anteroposterior and transverse diameters of the inlet and midpelvis were measured by x-ray pelvimetry (Colcher-Sussman technique).[13] Maternal pelvimetry was performed in each case after 37 weeks' gestation and before either the active phase of labor or intravenous oxytocin administration. This method consists of simple positioning of the patient in two views (lateral and anteroposterior). With each view an appropriately positioned ruler is included on the respective film for rapid and direct mensuration of the above-mentioned diameters. On the basis of a sum of the transverse and anterior-posterior diameters of the pelvic inlet as well as that of the midpelvis, an adequate pelvic size is defined as being >22 cm for the inlet and >20 cm for the midpelvis.[13]

The method of determining fetal-pelvic index values is as follows:[12] Individually measured anteroposterior

and transverse diameters of the fetal cranium, fetal abdomen, maternal pelvic inlet, and maternal midpelvis are used to compute respective circumferences of the fetal head (HC), fetal abdomen (AC), maternal pelvic inlet (IC), and maternal midpelvis (MC) by the equation: $C = (TD + APD) \times 1/2\ \pi$. On the basis of four circumference differences between the fetus and the maternal pelvis (HC-IC, HC-MC, AC-IC, AC-MC), a fetal-pelvic index value is derived from the sum of the two most positive circumference differences. A positive fetal-pelvic index value identifies a fetus that is larger than the maternal pelvis (presence of fetal-pelvic disproportion), and a negative fetal-pelvic index value identifies a fetus that is smaller than the maternal pelvis (absence of fetal-pelvic disproportion).

To provide comparative data, two other means of identifying fetal-pelvic disproportion were analyzed (Colcher-Sussman x-ray pelvimetry[13] and ultrasonographically determined estimated fetal weight of ≥4000 gm according to Shepard tables[14]). Results of the measurement and fetal-pelvic index data were not available to the clinicians managing the labors, and the investigators were not informed of the delivery outcomes. All three methods were compared with regard to delivery outcome and their respective accuracy of predicting the presence or absence of fetal-pelvic disproportion. This study was reviewed and approved by the institutional review board. Data were analyzed by Fisher's exact, χ^2, and independent two-tailed t tests, where appropriate.

Results

Of the 65 study participants, 18 (28%) failed to progress in labor and required a repeat cesarean delivery. Forty-seven (72%) were delivered vaginally without operative intervention. The two groups were comparable with regard to maternal age and parity. However, when compared with the vaginal delivery group, a greater proportion of nonwhite patients was observed in the cesarean group. The mean gestational age at the time of delivery was 39.5 ± 1.8 weeks for the cesarean group and 39.1 ± 1.4 weeks for those delivered vaginally.

Results of the mean birth weight, fetal ultrasonographic, and maternal x-ray pelvimetry measurement data are given in Table I. Mean birth weights and fetal head circumferences for both groups were similar. However, when compared with those who were delivered vaginally, the mean fetal abdominal circumference was significantly larger ($p < 0.025$) and the mean maternal inlet and midpelvic circumferences were significantly smaller ($p < 0.001$) in the cesarean group. Moreover, the measurement parameters contributing most often to observed fetal-pelvic disproportion were the respective fetal abdominal and maternal midpelvic circumferences, not the fetal head circumferences.

Delivery outcomes for the three methods tested are given in Table II. When ultrasonographically determined estimated fetal weight was used alone, with ≥4000 gm as the threshold weight for fetal-pelvic disproportion, the sensitivity was 0.11, specificity 0.96, and overall predictability 0.72. When x-ray pelvimetry was used alone, with a contracted maternal pelvis defined as either <22 cm for the inlet or <20 cm for the midpelvis, the sensitivity was 0.17, specificity 1.00, and overall predictability 0.77. Because of their low sensitivities, neither of these techniques provided accurate identification of fetal-pelvic disproportion.

Of the 18 women requiring repeat cesarean delivery

*Reason for operative delivery: cesarean, failure to progress in active phase (cervical dilatation >5 cm); operative vaginal, difficult midforceps or shoulder dystocia.

†Numbers in parentheses are patients with persistent occipitoposterior fetal presentation.

for failure to progress in labor, 13 demonstrated positive fetal-pelvic index values (sensitivity, 0.72) and five had negative index values (false negative). The five cases with false-negative fetal-pelvic index values deserve further discussion. Four of these five fetuses persisted in an occipitoposterior position and failed to progress in labor. The fifth fetus presented in an occipitoanterior position and had a birth weight of 3920 gm. Although no cephalopelvic disproportion was observed, a small degree of abdominal-midpelvic disproportion was present, and cervical dilation stopped at 6 cm.

All 47 vaginally delivered patients had negative fetal-pelvic index values (specificity, 1.00; negative predictability, 0.90). Moreover, all 13 women with positive fetal-pelvic index values required a repeat cesarean delivery (positive predictability, 1.00; Table II).

Delivery outcomes and fetal-pelvic index data relative to the indication for the previous cesarean section are given in Table III. The indications were divided into the following categories: cephalopelvic disproportion or failure to progress, fetal distress, breech presentation, and other (placenta previa, $n = 1$; abruptio placentae, $n = 2$; preeclampsia-eclampsia, $n = 2$; and unknown, $n = 1$). Of the 31 women with a previous cesarean delivery because of cephalopelvic disproportion or failure to progress, 18 (58%) were delivered vaginally. In contrast, when the previous cesarean section was performed because of fetal distress, nine (64%) of 14 were delivered vaginally. Of the 20 women with a history of previous cesarean section as a result of breech presentation and "other" indications, all were delivered vaginally. Sensitivity, specificity, and predictability of the fetal-pelvic index, relative to the indication for the previous cesarean section, are given in Table III.

Overall, malposition was observed in 10 fetuses—nine occipitoposterior presentation and one frank breech (Table III). Of the nine fetuses presenting in persistent occipitoposterior position, seven failed to progress in labor and a cesarean section was necessary (fetal-pelvic index values ranged from +1.1 to −5.0); two were delivered vaginally (fetal-pelvic index values were −6.9 and −8.8). The fetus presenting in a frank breech position was delivered vaginally with a fetal-pelvic index value of −7.8.

Comment

In management of a pregnant woman with a history of a previous cesarean delivery, the following three questions should be addressed: (1) What is the appropriate mode of delivery for this pregnancy? (2) When vaginal delivery is being considered, will labor compromise the safety of the fetus and mother? (3) Can the presence or absence of fetal-pelvic disproportion be identified prospectively in women attempting vaginal birth after previous cesarean delivery?

The answer to the first question dates back to Cragin's 1916 article, entitled "Conservatism in Obstetrics," in which he stated "The usual rule is once a cesarean always a cesarean."[15] Although Cragin's usual rule was not supported with data, it was applicable to the times in which he practiced. Subsequently, fear of rupture of a previous uterine scar was universally accepted.[16] By 1978, approximately 99% of American women with a history of a primary cesarean section underwent an automatic repeat cesarean of subsequent deliveries.[4] Thus for more than 60 years obstetricians believed automatic repeat cesarean to be the appropriate mode of delivery for women with a history of primary cesarean section. In 1991, this belief may not be appropriate for the majority of women, and vaginal delivery should be considered in selected cases.

Sensitivity	Specificity	Predictability	
		Positive	Negative
0.87	1.00	1.00	0.92
0.94	0.94	0.94	0.94
0.86	1.00	1.00	0.95
0.71	0.95	0.94	0.75
0.72	1.00	1.00	0.90

The answer to the second question has been addressed extensively during the past two decades. Since 1970 the cesarean section rate has increased from 5.5% to 24.4%, making cesarean section the most frequently performed major surgical procedure in United States hospitals.[17] Concern over the dramatic rise in the cesarean section rate in the United States and the relative increase in the number of elective repeat cesareans led to a formal reexamination of the beliefs and fears governing cesarean delivery.[18] Four diagnostic categories were identified as primarily responsible for the increasing cesarean rate: repeat cesarean (35%), dystocia (30%), breech presentation (10% to 15%), and fetal distress (10% to 15%). Although the threat of malpractice was thought to be a consideration, the National Institutes of Health Consensus Report panel could not accurately assess the impact of defensive medical practices.

Because of the lack of objective justification for the overall increasing cesarean section rate, attempts have been made to reduce it. Moreover, a particular focus has been on vaginal birth after previous cesarean delivery. During the past 5 years, a number of investigators have addressed the prevailing negative attitude toward vaginal birth after previous cesarean delivery with reports on uterine rupture,[19] labor trials and vaginal birth after previous cesarean delivery,[11, 20] new American College of Obstetricians and Gynecologists guidelines for vaginal birth after previous cesarean delivery,[21] programs to lower cesarean section rates,[22] perinatal mortality rate after vaginal birth after previous cesarean delivery,[23] vaginal delivery after more than one previous cesarean,[24, 25] maternal risks in vaginal birth after previous cesarean delivery,[26] vaginal birth after previous cesarean delivery in cases of macrosomic fetuses,[27] and vaginal birth after previous cesarean delivery in cases of multifetal gestations and breech fetuses.[28] On the basis of these reports, the safety of a labor trial and subsequent successful vaginal delivery of the majority of women attempting vaginal birth after previous cesarean delivery has been established. As a result, automatic repeat cesarean section as the primary cause of the rising cesarean birth rate is being challenged.[29-32]

The answer to the third question is the principal objective of this report. When a vaginal birth after previous cesarean section is considered, the most important issue is appropriate patient selection. Central to this selection process is the ability to identify fetal-pelvic disproportion. This issue has not been addressed adequately because an accurate method of identifying the presence or absence of fetal-pelvic disproportion has not been available.

In 1986 we introduced the fetal-pelvic index as an accurate method of prospectively identifying the presence or absence of fetal-pelvic disproportion.[12] In three subsequent studies we reported on the reproducible accuracy of this method in women with the following conditions considered at high risk for cesarean section: (1) macrosomic fetus,[33] (2) labor induction,[34] and (3) an abnormal labor pattern requiring augmentation.[35] In this study we report on the efficacy of fetal-pelvic index as a method of prospectively identifying the presence or absence of fetal-pelvic disproportion in women attempting vaginal birth after previous cesarean delivery. On the basis of these data, we believe the fetal-pelvic index provides an accurate method of identifying the presence or absence of fetal-pelvic disproportion in these women. With this approach, proper selection of those women who will successfully be delivered vaginally can be made. When the managing obstetrician is able to identify the absence of fetal-pelvic disproportion, a more active management of labor can be pursued with confidence. Conversely, when the fetal-pelvic index is positive, prolonged unsuccessful labor trials can be prevented in those women destined to fail. The impact (financial, emotional, and medical) of being able to identify fetal-pelvic disproportion and predict delivery outcome in more than 90% of patients with a previous cesarean delivery is potentially enormous.

Findings of this study support those of our previous reports in which various x-ray pelvimetry measurement criteria and various ultrasonographically derived estimated fetal weights, when used alone, do not predict fetal-pelvic disproportion accurately.[12, 33-35] In Table IV, a summary of data from the four previous fetal-pelvic index studies and the present study is given. Overall, the sensitivity of the fetal-pelvic index is 0.82, specificity is 0.99, positive predictability is 0.98, and negative predictability is 0.90. Of the 19 cases with a negative fetal-pelvic index requiring a cesarean section (false negatives), 17 fetuses demonstrated a persistent occipitoposterior position and failed to progress in labor.

Although the predictive accuracy of the fetal-pelvic index in each of our studies has been highly reproducible, our findings need to be substantiated by other investigators before a formal recommendation can be made to all clinicians. Therefore we hope more centers will evaluate the efficacy of the fetal-pelvic index in women with all conditions at high risk for cesarean delivery.

Acute myocardial infarction associated with prostaglandin E_2

William J. Meyer, MD, Steven L. Benton, MD, Timothy J. Hoon, PharmD,
Daniel W. Gauthier, MD, and Valerie E. Whiteman, MD
Chicago, Illinois

Prostaglandin E_2 is rarely associated with serious maternal side effects when used for second-trimester pregnancy termination. Acute myocardial infarction complicating therapeutic pregnancy termination with prostaglandin E_2 in a patient with chronic glomerulosclerosis and severe hypertension is reported. (AM J OBSTET GYNECOL 1991;165:359-60.)

Key words: Prostaglandin E_2, myocardial infarction, pregnancy termination

Prostaglandin E_2 (PGE_2) is the preferred agent for second-trimester pregnancy termination, replacing instrumented evacuation of the uterus and intraamniotic injection of abortifacient agents. It is also useful for cervical ripening and induction of labor in pregnancies complicated by serious maternal illness. Side effects are usually mild and include nausea, vomiting, pyrexia, diarrhea, and occasionally hypotension. We report a case of severe hypotension and acute myocardial infarction associated with PGE_2 in a patient undergoing therapeutic termination of pregnancy.

Case report

A 38-year-old black woman, gravida 3, para 0-0-2-0, with chronic hypertension and renal insufficiency as a result of chronic glomerulosclerosis was seen by her physician with a 2-day history of symptoms consistent with congestive heart failure. Obstetric history was remarkable for two fetal deaths at 27 weeks' gestation because of preeclampsia. Initial evaluation revealed a blood pressure of 260/140 mm Hg, bilateral rales, pretibial edema, and hyperreflexia. Electrocardiogram demonstrated normal sinus rhythm with a rate of 85 beats/min. Mild cardiomegaly and slight pulmonary edema were present on chest x-ray film. Echocardiogram revealed moderate concentric left ventricular hypertrophy with mild global hypokinesis. A gestation of 19 weeks was estimated by ultrasonography. Significant laboratory values included blood urea nitrogen, 51 gm/24 hours; creatinine, 5.0 mg/dl; hemoglobin, 6.7 gm/dl; and uric acid, 6.1 mg/dl. Liver function test results and platelet count were normal. Magnesium sulfate was given, a nitroprusside infusion was started, and the patient was transported to our hospital with the diagnosis of possible superimposed preeclampsia.

The nitroprusside was subsequently gradually withdrawn in our intensive care unit, and the patient was stabilized on a regimen of a hydralazine infusion with intermittent intravenous methyldopa and furosemide. Hemoglobin was increased to 9.4 gm/dl after a transfusion of 2 units of packed red blood cells. Liver function test results, platelet count, and urine output remained normal, with a urine protein of 2.3 gm/24 hours. Two days after admission, a therapeutic termination of pregnancy was requested by the patient after she was counseled regarding the maternal risk of continuing the pregnancy.

A 20 mg PGE_2 vaginal suppository was administered while the patient was continuously monitored in the cardiac care unit. Blood pressure was 180/98 mm Hg while she was receiving a hydralazine infusion of 8 mg/hr with no other antihypertensives (except intravenous furosemide) given within the previous 22 hours. Approximately 30 minutes after administration, the patient became hypotensive with bradycardia, and she experienced cardiovascular collapse. Rhythm strips documented transient complete heart block followed by ventricular fibrillation. The heart was defibrillated, and she was then stabilized with vasopressors, lidocaine, an intraaortic balloon pump, and ventilatory support. A 12-lead electrocardiogram revealed an acute inferior wall myocardial infarction, which correlated with a new inferior wall hypokinesis on repeat echocardiogram. Cardiac catheterization revealed angiographically normal coronary arteries. Hemodynamic status improved rapidly, and the patient was off assisted ventilation, balloon pump, and vasopressors within 24 hours. Spontaneous delivery of the fetus occurred 8 hours after the myocardial infarction. Urine output was maintained with only slight elevation of the creatinine level to 7 mg/dl, and recrudescent hypertension was controlled with oral medications. The remainder of the hospital course was uncomplicated.

Comment

Severe cardiovascular complications associated with PGE_2 are rare. PGE_2 is rapidly absorbed after vaginal administration and can produce hypotension as a result of direct arteriolar vasodilation. Sampson et al.[1] re-

ported a mild decrease in mean arterial pressure after PGE_2 administration for midtrimester pregnancy termination in patients with severe preeclampsia receiving antihypertensive agents. None of these patients had serious complications.

The time interval between PGE_2 administration and the circulatory collapse and myocardial infarction in our patient would imply a relationship between these events. Preexisting coronary artery disease did not complicate this case. We propose that PGE_2 acted synergistically with the antihypertensive therapy to cause profound hypotension, resulting in coronary hypoperfusion and myocardial infarction. PGE_2 has a short biologic half-life, and the rapid recovery from cardiovascular shock observed in this case also is compatible with a causal relationship. PGE_2-induced coronary artery spasm seems unlikely because it has been shown to possess coronary artery relaxant effects.[2] In any case PGE_2 should be used with caution in patients receiving vasoactive antihypertensive medications, especially when preexisting cardiac disease or risk factors are present.

CA 125 regression: A model for epithelial ovarian cancer response

Richard E. Buller, MD, PhD, Michael L. Berman, MD, Jeffrey D. Bloss, MD, Alberto Manetta, MD, and Philip J. DiSaia, MD
Orange, California, and Iowa City, Iowa

The rate of decline of CA 125 in effectively treated epithelial ovarian cancer is described by the exponential regression curve CA 125 = EXP [$i - s$ (days after surgery)]. In this equation i, the y-axis intercept, measures initial tumor burden whereas s, the slope of the regression curve, is determined by the extent of cytoreductive surgery and the subsequent response to chemotherapy. Departure from the regression curve uniformly results in progressive disease. In patients whose cancers had been completely removed, we calculated the mean half-life of CA 125 to be 10.4 days (range 4 to 21). In this case $s = 0.0835$ and characterizes the ideal regression rate. The model predicts that high-dose cisplatin chemotherapy ($s = 0.0671$) is more effective than low-dose cisplatin ($s = 0.0380$) ($p < 0.03$) in eliminating residual cancer. Because s can be calculated within 2 to 3 months of treatment and then compared with s for the ideal regression curve and with the values of s reported for standard chemotherapy, evaluation of any new treatment protocol can be facilitated with this method. (AM J OBSTET GYNECOL 1991;165:360-7.)

Key words: CA 125, exponential regression, chemotherapy

Ovarian carcinoma is the fourth most common cause of death among American women.[1] Aggressive surgical cytoreduction and subsequent cisplatin-based chemotherapy have helped prolong disease-free survival for women with advanced disease.[1,2] Our ability to monitor disease status during therapy has been facilitated by measurement of the tumor-associated antigen CA 125. Bast et al.[3] and others[4,5] have shown that changes in serum CA 125 levels reflect progression or regression of epithelial ovarian cancer >90% of the time. That is to say, increases in serum CA 125 levels reflect disease progression whereas declines in serum CA 125 levels reflect a response to therapy. Thus by monitoring CA

125 levels during treatment, it has been possible to predict response to therapy in the absence of clinically measurable disease and to prognosticate survival.[6-10] Most clinical trials still rely on second-assessment celiotomy to determine the initial effectiveness of chemotherapy because survival data, which are the only realistic end point of treatment efficacy, can take years to generate. Simply measuring serum CA 125 levels before second-assessment celiotomy is not helpful because the negative predictive value in a patient with stage III or stage IV epithelial ovarian cancer is only 50%.[11] Reliance on second-assessment celiotomy is costly. Awaiting accrual of survival data can be inefficient. Such an approach may result in missed opportunities to initiate phase II drug studies in women with a small tumor burden before depletion of marrow reserves. This study was designed to develop a model of tumor response by considering the serum CA 125 level as a continuous variable that is reflective of tumor growth or regression for those epithelial ovarian cancers that are marker positive. As the model was developed, we used it to characterize the initial clinical responsiveness of CA 125–secreting epithelial ovarian cancers. The model can be used to compare the relative efficacy of different therapeutic regimens. In a separate communication we will show how initial responsiveness is predictive of findings at second-look celiotomy and translates into overall survival.

Material and methods

Sixty-four patients with advanced ovarian epithelial carcinoma who were treated at the University of California, Irvine (UCI), or its affiliated hospitals, beginning in January 1986 through June 1990, form the population of this study. Women treated during this time interval who were marker negative or who did not have sequential measurements of serum CA 125 levels beginning early in therapy could not be evaluated. Patient characteristics and follow-up are summarized in Table I. The average age at diagnosis was 62.6 years (range 43 to 80). Eighty-four percent of patients in this study had stage III or stage IV disease. Ninety-four percent of the lesions were grade 2 or 3. We also included two patients with dual primary endometrial and ovarian lesions that were confined to the pelvis and were CA 125 positive. All histologic types of epithelial ovarian cancer were included. Seventeen patients died of progressive or recurrent ovarian carcinoma during the study interval. Three patients died apparently of causes other than tumor recurrence 6.7, 6.8, and 35.9 months into therapy without evidence of disease. The mean follow-up for all patients was 15.6 months (range 2 to 48).

Treatment consisted of biopsy only for seven patients, all operated on at outside facilities and referred to UCI for chemotherapy. In 13 patients cancer was completely resected whereas 26 underwent cytoreduction to residual cancer >2 cm and 18 had residual disease <2 cm. All patients were treated with cisplatin-based chemotherapy. The chemotherapy regimens planned were as follows: CAP [cisplatin, approximately 50 mg/m^2; doxorubicin (Adriamycin, Adria, Columbus, Ohio), approximately 50 mg/m^2; and cyclophosphamide (Cytoxan, Bristol-Myers, Syracuse, N.Y.), approximately 50 mg/m^2] in eight patients for eight cycles; low-dose cisplatin, approximately 50 mg/m^2, and Cytoxan, approximately 500 mg/m^2) in 30 patients for eight cycles; high-dose cisplatin approximately 100 mg/m^2, and Cytoxan, approximately 1000 mg/m^2, in 21 patients for four cycles. Other treatments included cisplatin, approximately 75 mg/m^2, and primary intraperitoneal cisplatin or carboplatin plus intravenous Cytoxan or Adriamycin, or both, for five patients. Twenty-three of the patients included in the study were randomized to treatment regimens on a Gynecologic Oncology Group protocol designed to compare high-dose and low-dose cisplatin chemotherapy. Four patients, two on the low-dose cisplatin regimen and two on CAP, did not complete the planned chemotherapy because of progression of disease.

Statistical evaluations included least-squares regression analysis of CA 125 data as a function of time. Comparison of means was achieved by the unpaired Student t test requiring $p < 0.05$ for statistical significance. When categorical variables were analyzed, we used χ^2 with Yates' correction as indicated.

Model development

Levels of CA 125 were plotted against time with the day of surgical cytoreduction recorded as time 0. If a

*Includes a preoperative CA 125 level in the regression analysis.

†Includes all postoperative CA 125 levels up to and including the first level <35 U/ml.

‡Includes all postoperative levels of CA 125 up to, but excluding, the first level <35 U/ml.

§The first data point is postoperative in this analysis.

patient underwent biopsy only, with the vast majority of tumor left in situ, time 0 was the first day of chemotherapy. CA 125 levels in serum drawn preoperatively were assigned to day 0 in the absence of serum drawn on the day of surgery. Thirty-two patients had preoperative CA 125 levels measured. For the rest the first determination was after surgery and before the first dose of chemotherapy, which was begun on mean postoperative day 19 (range 4 to 42). We performed regression analysis of the data to evaluate both linear and exponential decay patterns. Most patients did not have CA 125 levels measured every few days after the initiation of therapy. Therefore we tested the effects of omitting some data points in a known setting where complete CA 125 data were available. The four possible combinations evaluated were: (1) preoperative CA 125 available, with data plotted to include all postoperative levels up to and including the first normal CA 125 level, ≤ 35 U/ml; (2) preoperative CA 125 level and only elevated postoperative CA 125 levels (>35 U/ml); (3) postoperative CA 125 levels only, to the first normal level; (4) only elevated postoperative CA 125 levels. The results of this analysis for a typical patient are shown in Table II. The models tested were:

$$\text{Serum CA 125 level} = i - s\ (\text{days after surgery})\ (\text{linear regression}) \tag{1}$$

$$\text{Serum CA 125 level} = \text{EXP}(i - s\ [\text{days after surgery}])\ (\text{exponential regression}) \tag{2}$$

where EXP $= 2.718$, i is the y-axis intercept, which reflects initial tumor burden of CA 125–secreting cells, and s is the slope of the regression curve, which is representative of the rate of disappearance of CA 125 from the serum. This rate reflects the composite effects of surgical cytoreduction and effective chemotherapy. When data are plotted, it is more convenient first to perform a natural logarithmic transformation on equation 2, which gives equation 3:

$$\ln\ (\text{serum CA 125}) = i - s\ (\text{days after surgery}) \tag{3}$$

Equations 2 and 3 are mathematically equivalent.

Table II shows that for each set of data the correlation coefficient r is the highest for the exponential model. When r approaches 1.0, a linear relationship exists; the lower the r value, the looser the relationship. When an analysis of variance of the regression curve is carried out as determined by the F ratio test, the exponential model gives p values with a higher significance than the corresponding linear model. In each case the best-fit, lowest p value is represented by the data where preoperative levels of CA 125 are included in an analysis that proceeds through the first normal level of CA 125 ($r = 0.98$, $p < 0.0009$). However, by virtue of the high r and low p values for each of the four combinations of data points, we conclude that the exponential model can be used to approximate s and i even if we are unsure of the preoperative level of CA 125 or precisely when the CA 125 level normalized.

The CA 125 regression curve for a typical patient who responds completely to therapy is represented by the solid line in Fig. 1. In this case $r = -0.98$ and $p < 0.0009$. This plot results in a straight line. When the combination of surgery and chemotherapy is ineffective, as for the patient whose CA 125 data is plotted as the dashed line in Fig. 1, $r = -0.09$ implies a poor fit of the model. The F ratio approaches 0 and p is much greater than 0.05 ($p = 0.86$) for the best-fit regression line. This analysis was carried out for all of the 64 patients. It was possible to calculate s within 30 to 60 days of surgery. In 12 patients serum CA 125 levels never normalized, and clinical progression of disease occurred. For these patients a regression curve that used all data points up to the first increase in serum CA 125 was generated. The mean number of data points for all patients was 4.5 (range 2 to 10). For 54 patients, three or more measurements of CA 125 were available. For 10 patients only two data points were

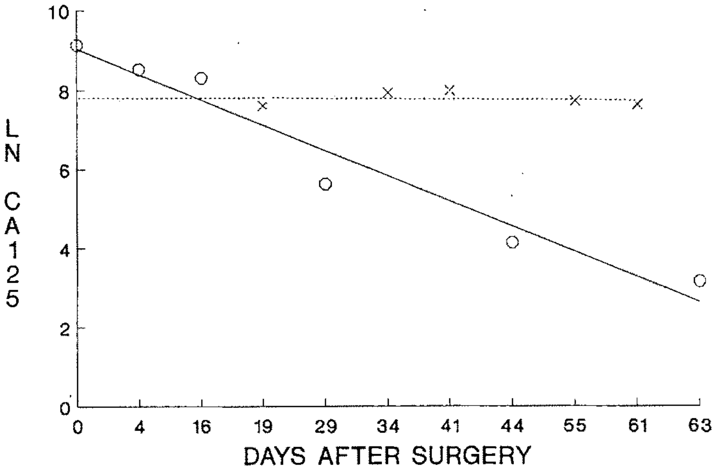

Fig. 1. Exponential regression curves. Comparison of CA 125 regression for responsive cancer (o——o) and unresponsive cancer (x – – – x). Normal level of CA 125 is 35 U/ml (LN 35 = 3.56). *LN,* Natural logarithm.

available. If these patients are excluded, the mean r value for the regression curves was -0.94 indicating that the data fit the model quite well.

Tumor grade, tumor stage (according to International Federation of Gynecology and Obstetrics), and the extent of cytoreductive surgery are several parameters that can influence survival of the patient with ovarian cancer. To develop our model more completely, we investigated the influence of these factors on the regression parameters i and s. These data appear as Table III.

Residual disease. Residual disease was quantitated as none, largest nodule >2 cm, or in between these two parameters. Patients whose tumor was not resected were distinguished from the groups with residual disease and analyzed separately. The values of s and i were calculated for these data, which were stratified on the basis of residual disease, and are presented in Table III. This table shows the trend for more rapid regression of CA 125 as the volume of residual disease decreases from the biopsy-only cases where s is 0.0331 to a value of 0.0835 for the cases with no residual disease. The difference between the two extreme values of s is significant at a p level of 0.015. The difference between the rate of regression for biopsy-only cases and residual disease of <2 cm is also significant ($p < 0.015$). No other pairwise comparisons of s reached significance. The values of i reflect the initial tumor burden. The i values were not statistically different between groups.

The group of patients from Table III who underwent complete resection of ovarian cancer also provides us with the data necessary to calculate the serum half-life of CA 125. When this group of patients is considered as a whole, the mean serum half-life of CA 125 is calculated to be 10.8 ± 5.5 days (range 4 to 21 days).

Stage of disease. Clinical experience dictates that tumor burden generally increases with the stage of disease. We tested our model on this point by stratifying patients on the basis of FIGO stage and generated values for i and s. These data are also shown in Table III. The y-axis intercepts, which are reflective of the initial tumor burden, increased from 5.996 to 6.936 to 7.636 as stage advanced from II to III to IV. Only the difference in i for stages II and IV reached statistical significance ($p < 0.04$). When the values of s were compared pairwise between stages, again only the difference between stage II and stage IV was significant ($p < 0.05$). This result is consistent with the fact that all of the patients with stage II had no residual disease, while the patients with stage IV usually had bulky residual disease.

CAP	6	0.0320 ± 0.0186	6.826 ± 2.439
Low-dose cisplatin	25	0.0380 ± 0.0276	6.542 ± 1.215
High-dose cisplatin	17	0.0671 = 0.0549	7.888 ± 1.546

on the basis of tumor grade. There was a trend toward more rapid response by the more undifferentiated tumors: The value of s increased with increasing grade. The difference in tumor burden was significant only when grade 1 tumors were compared with grade 2 tumors ($p < 0.03$).

Clinical correlation. The clinical relevance of the parameters s and i was determined by grouping the patients according to their response to therapy. Three broad classifications were used: (1) progressive disease during chemotherapy, (2) complete response to therapy on the basis of clinical evaluation and normalization of the serum CA 125 level, followed by recurrence of cancer, and (3) a complete response to therapy with no current evidence of cancer. The mean values of s and i were calculated for these groupings and are displayed in Table IV. This table shows that the tumor burden, as reflected by i, was the same for all groups ($p > 0.24$). On the other hand, there was a steady increase in the rate of decline of the serum CA 125 level, from those with progressive disease ($s = 0.0250$), to those who responded then had recurrence ($s = 0.0497$), to those who remain without disease ($s = 0.0783$). All pairwise comparisons of s were statistically significant ($p < 0.02$). Thus the more rapid the decline in serum CA 125 level, as measured by s, the greater the likelihood of clinical response and cure.

Chemotherapeutic regimen. Finally, we investigated the effects of different chemotherapy regimens. Values of s and i were calculated on the basis of our exponential model. These results appear in Table V. Table V shows that the patients in the high-dose cisplatin group had a higher value of i ($p < 0.04$) only when compared with the value of i for the low-dose cisplatin-treated group. Other pairwise comparisons, e.g., high versus CAP ($p = 0.23$), and low versus CAP ($p = 0.68$), were not significant. Evaluation of treatment response, as measured by the value of s, showed a significant difference for high-dose cisplatin chemotherapy compared with low-dose cisplatin ($p < 0.03$) but not the CAP regimen ($p = 0.14$). Similarly, there was no difference between the CAP regimen when compared with the low-dose cisplatin regimen ($p = 0.62$). For the purpose of these analyses, patients who had complete cytoreduction were removed to prevent bias.

The ideal CA 125 regression curve is generated by monitoring serum levels after complete resection of cancer. For any chemotherapeutic regimen designed, comparison of the rate of CA 125 regression relative to the ideal regression curve provides a measure of its relative effectiveness. The more effective the treatment, the closer the regression line comes to the ideal. Fig. 2 illustrates this point. This figure results from plotting the mean regression curves, which have been normalized for the same tumor burden (i), for complete resection, high-dose cisplatin therapy for residual disease, and low-dose cisplatin therapy for residual disease. When high-dose cisplatinum therapy is used, CA 125 regression approaches that seen for the patient with complete cytoreduction; this value is statistically different from that of low-dose cisplatin therapy ($p < 0.03$).

These data also justify the omission from analysis of patients whose cancers are completely resected when types of chemotherapy are compared. For those patients s approaches the ideal regression curve by virtue of the surgery alone, so that there can be no difference on the basis of chemotherapy over the short term.

Contingency tables were constructed to evaluate the possible influence of tumor grade, extent of residual disease, or FIGO stage. Table VI shows the distribution of covariables for the different chemotherapies. In each instance the calculated value of χ^2 was low and not statistically significant. Thus the different chemotherapy groups were homogeneous from the standpoint of those variables that could have introduced bias.

There was a statistically different mean age between chemotherapy groups. Patients treated with the high-dose cisplatin regimen were slightly younger (mean 59 years) than the group treated with the low-dose cisplatin (mean 66 years) ($p = 0.006$). There was no age difference between the high-dose cisplatin group and the CAP chemotherapy group ($p = 0.25$).

Comment

Most authors[3, 5, 8, 12, 13] agree (1) that for CA 125–positive tumors the level of CA 125 reflects tumor burden and (2) that for a given individual the change in CA 125 level accurately reflects disease status. These observations hold true even when there is no radiologic or physical evidence of residual disease after cytore-

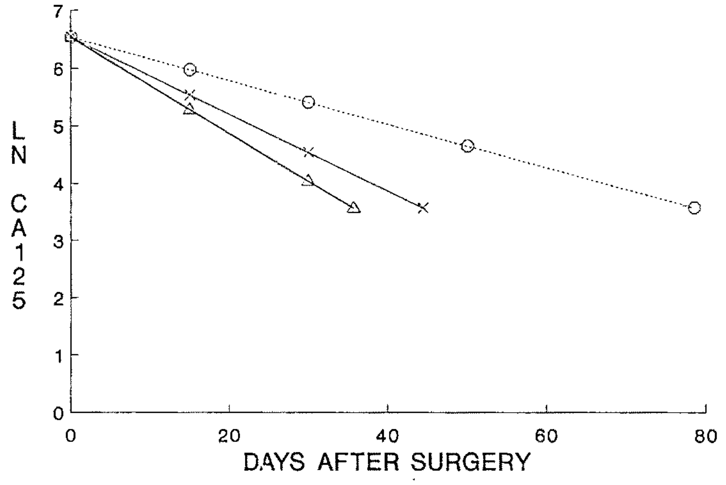

Fig. 2. Cisplatin dose-response curve. Comparison of rate of decline in serum CA 125 levels for patients with residual disease treated with low-dose cisplatin-Cytoxan (o——o) or high-dose cisplatin-Cytoxan (x——x) to ideal regression curve (Δ——Δ) generated from patients with no residual disease. LN (35) = 3.56, which is considered the normal level of CA 125. *LN,* Natural logarithm.

ductive surgery. That is to say, a rising CA 125 level correlates well with disease progression and a falling CA 125 level accurately reflects the combined effects of surgery and or effective chemotherapy. This formula provides a model to measure the rate of change of serum CA 125 level as a function of initial tumor burden and subsequent response to treatment:

$$\text{Serum CA 125 level} = \text{EXP}(i - s\ [\text{days after surgery}])$$

The value of s can be calculated within 30 to 60 days of initial surgery for the patient who is started promptly on a regimen of chemotherapy. The value of s reflects the composite effects of surgery and effective chemotherapy. For most patients it is not possible to separately quantitate the relative effects of surgery alone versus those of chemotherapy alone. However, we can approximate these relative effects with the use of data that have been stratified on the basis of residual disease from Table III. The seven patients who had biopsy only and did not undergo cytoreductive surgery are essentially a group treated by primary chemotherapy. The 13 patients who had no residual disease after surgery are our closest approximation to surgery alone even though they also received chemotherapy. The difference in s between these groups was significant at the $p < 0.02$ level, which indicates that cytoreductive surgery is more effective than chemotherapy in producing an initial therapeutic response. This result lends support to the approach of most gynecologic oncologists, who reoperate on patients with ovarian cancer who are referred after an open-and-close operation at an outside institution.[14-17]

The mean serum half-life of 10.8 days that we report is larger than the 4.8-day half-life reported by Canney et al.,[1] who used data from a single patient with completely resected early disease to determine half-life. The difference is explained by the fact that our data base included patients with stage III and IV disease who undoubtedly had residual microscopic foci of cancer that were favorably influenced by chemotherapy. The half-life of CA 125 in other patients also was as short as 4 days even though they had residual macroscopic disease. In these cases the residual disease was either extremely sensitive to chemotherapy or not responsible for secreting CA 125 into the serum. Thus we prefer to report the mean serum half-life and to use it, rather than the minimum half-life value of 4 days, to calculate the ideal regression curve.

Most patients did not have CA 125 levels measured every few days after the initiation of therapy. Before this retrospective study, our standard was to check CA 125 levels immediately before each cycle of chemotherapy. Careful evaluation of the data in Table II indicates that the unavailability of data points from the preoperative time inclusively through normalization of the CA 125 levels does not seriously affect our calculated values of s and i. For the incomplete data sets, the model was still useful since the r values ranged from -0.98 to -0.96 and p ranged from 0.0009 to 0.03345. Our standard now is to measure serum CA 125 before surgery, several days after surgery, on the first day of chemotherapy, and weekly during the initial 6 weeks of chemotherapy to try to refine calculated values of s.

The principle of generating a regression curve is not new. Schlaerth et al.[18] applied this concept to gestational trophoblastic neoplasia in 1981, thereby identifying patients who would require chemotherapy on the basis of departure from the normal regression curve of β-human chorionic gonadotropin. Our study characterizes regression curves for the coelomic epithelial antigen CA 125 in epithelial ovarian cancers and also suggests that clinical outcome can be predicted reliably on the basis of these curves. By logical extension, regression curves that use other tumor markers such as NB/70K, CA 19-9, lipid-associated sialic acid, etc., could be described similarly for those tumors that elaborate these tumor-associated antigens. Furthermore, we suggest that these regression curves or a multivariate regression curve for a spectrum of tumor-associated antigens might predict clinical outcome even more precisely.

Studies have shown that ovarian epithelial carcinomas have heterogeneous immunohistochemical staining properties for CA 125.[13] We do not have evidence at this time that the chemotherapeutic response of the CA 125–secreting cells is the same as that of those that do not secrete CA 125. If our model is to accurately describe effective treatment of epithelial ovarian cancer, this factor forms a critical assumption. Further justification of this assumption can be generated by studying simultaneous markers, which are secreted by different cell types, as well as by using second-assessment celiotomy and disease-free survival as additional end points. These analyses will form the basis of a subsequent report.

Our model also assumes that there is a relationship between the amount of residual tumor after cytoreductive surgery and the serum CA 125 level. It is true that ascites[19] and other confounding variables such as tumor grade, histologic type, and heterogeneity may influence the serum level of CA 125; however, these parameters will be constant for a given patient. When mean pooled values of s for different treatment regimens are compared, it is thus critical to have enough heterogeneity between cohorts so that one covariable does not skew interpretation of the data.

Within biologic systems, dose-response curves generally are sigmoidal in shape.[20] In humans, it is unclear whether treatment with 50, 75, or ≥ 100 mg/m^2 of cisplatin per cycle reaches the plateau region of a typical dose-response curve or merely moves along the linear region of the curve. Ozols et al.[21] and others[22-24] have inferential evidence that taking cisplatin doses to toxic levels may favorably affect survival. When traditional methods of survival analysis are used, the studies necessary to prove this point may take years to mature. The model we have developed provides an eloquently simple means of addressing such clinically relevant issues in a timely fashion. We suggest that various treatment regimens be compared on the basis of the value of s relative to the ideal regression curve, as we have done by comparing low-dose cisplatin chemotherapy with high-dose cisplatin chemotherapy in Fig. 2. While our study groups were homogeneous with regard to surgical stage, grade, and extent of resection, there was a statistically younger patient population treated with the high-dose cisplatin regimen than with the low-dose regimen. Even though 36% of our patients were treated on a randomized basis, there was probably a tendency to treat the older patients whose treatment was not randomly assigned with a "less toxic regimen" in the 1986 to 1988 era. In general, there is a greater tendency for recurrence of disease in older patients[25] so that there could be an age bias influence of our results. On the other hand, there was also a statistically larger tumor burden ($p < 0.04$) for the high-dose regimen than for the low-dose regimen. Thus, since these are potentially offsetting influences, we must have additional patient accrual to solidify the evidence that the high-dose cisplatin regimen is more effective than the low-dose regimen.

In conclusion, the decline in serum CA 125 levels in patients with effectively treated epithelial ovarian cancer follows an exponential regression. These regression curves may be used to generate in vivo dose-response curves and to compare chemotherapeutic regimens. Strong divergence from the ideal regression curve uniformly results in treatment failure. Divergence can be determined within 30 to 60 days of initial surgery. When it occurs, we must begin trials of alternative chemotherapy that is designed to overcome drug resistance earlier than has been the case traditionally. The time has come to utilize the full weight of CA 125 data to make treatment decisions rather than to wait for the findings at second look or the reappearance of bulky disease.

Uterine rupture at term pregnancy with the use of intracervical prostaglandin E_2 gel for induction of labor

Ron Maymon, MD, Adrian Shulman, MD, Meir Pomeranz, MD, Michael Holtzinger, MD, Luis Haimovich, MD, and Charles Bahary, MD

Kfar Saba, Israel

Prostaglandin E_2 is a powerful oxytocic agent that reliably initiates labor, even in the presence of an unripe cervix. The low incidence of fetomaternal complication contributes to its universal use. We report a rare case of uterine rupture after intracervical application of prostaglandin E_2 gel. Thus far no prostaglandin compound or method of administration seems to be exempt from such a complication. (AM J OBSTET GYNECOL 1991;165:368-70.)

Key words: Prostaglandins, term pregnancy, uterine rupture

Numerous studies over the past decade have explored the promising results of topical application of prostaglandin E_2 (PGE_2) for cervical ripening or induction of labor without serious maternal or neonatal complications.[1] We present a case of uterine rupture after intracervical application of PGE_2 gel, which to the best of our knowledge is the first reported case of such a catastrophic complication of this agent.

A 28-year-old gravida 3, para 2 woman with two previous uncomplicated deliveries was admitted to the labor ward for induction of labor at 42 weeks' gestation of her third normal pregnancy. Her medical history was noncontributory. At admission the general physical examination and blood clotting studies were within normal limits. Fundal height was appropriate for gesta-

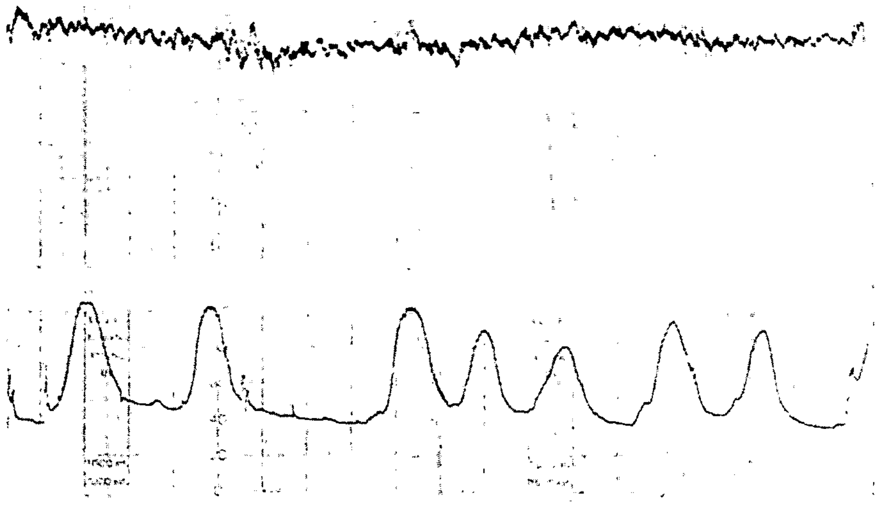

Fig. 1. Monitor tracing shows uterine tachysystole with normal reactive fetal response on external cardiotocographic monitoring.

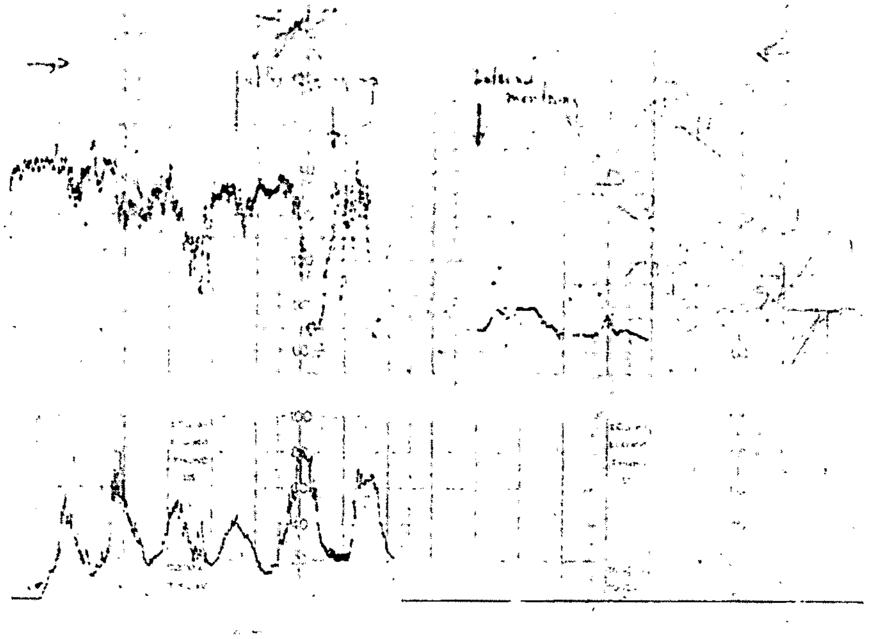

Fig. 2. Monitor tracing shows sudden fetal heart rate decelerations on scalp electrode and uterine tachysystole on external tocographic monitoring.

tional age, and the abdomen was soft with no uterine contractions. On vaginal examination, station of the vertex was −3; the cervix was 20% effaced and 2 cm dilated. The membranes were intact. Cardiotocographic monitoring, performed continuously for 30 minutes, showed normal fetal heart rate with good variability and no uterine contractions. In an attempt to ripen the cervix, the patient was given 0.5 mg PGE_2 gel (Prepidl dinoprostone gel, Upjohn Company) just below the level of the internal cervical os, as previously recommended.[1] One hour later, tachysystolic uterine contractions began and lasted for 20 minutes with no sign of fetal distress (Fig. 1). At this point the patient was given 75 mg meperidine hydrochloride to alleviate the pain and the uterine contractions were ameliorated. Four hours after the PGE_2 application, the cervix was fully dilated, vertex on right occipitotransverse position and the patient was in the lithotomy position when suddenly severe fetal bradycardia was recorded (Fig. 2). A female infant was delivered by rapid vacuum application. The infant weighed 3300 gm and had Apgar scores of 1 and 7 at 1 and 5 minutes, respectively.

Immediately after delivery the mother suddenly displayed signs of severe hemodynamic shock, which in spite of minimal vaginal bleeding, was discovered by pelvic examination to be a result of a ruptured uterus. Emergency laparotomy revealed an 8 cm rupture in the left lateral wall of the uterus, extending from the round ligament close to the internal cervical os. A total abdominal hysterectomy was performed. Postoperative and postnatal recovery was uneventful for both mother and infant.

Comment

Before initiating labor, biochemical changes take place in the connective tissues of the lower uterine segment and cervix. Irrespective of the strength of the uterine contractions, unless these biochemical changes have occurred, the cervix cannot efficiently dilate. Induction of labor with PGE_2 offers the advantages of both induction of further cervical ripening and promotion of myometrial contractility.[1, 2]

According to some authors, detectable myometrial activity is dose-related and more common after intravaginal versus intracervical PGE_2 application.[2] However, signs of myometrial hyperstimulation after intravaginal application of PGE_2 gel have been recorded in 0.6% to 6% of the cases, which is not thought to be more common than that found with oxytocin infusion alone and is virtually nonexistent with a 0.5 mg intracervical dose.[1, 2]

Episodes of fetal heart rate abnormalities and fetal distress, which are associated with uterine hyperstimulation, occur in $<1\%$ of the reported cases, and emergency cesarean sections are rarely necessary.[1]

This case shows that the use of PGE_2 gel at term pregnancy should be used cautiously because individual absorption rates are unpredictable and once absorbed it cannot be discontinued.

In patients who receive PGE$_2$ gel for induction of labor, the obstetrician should be aware of the need for conscientious monitoring, including continuous cardiotocodynomometry, frequent abdominal palpation, and meticulous monitoring of the patient's vital signs for prompt and early diagnosis of uterine rupture. Also, if long-standing hypercontractility occurs, the use of β2 selective sympathomimetic drugs should be considered to reverse this effect. The obstetric dilemma of whether the cervical route for administration of PGE$_2$ gel carries the same risk of uterine rupture as has been reported for other prostaglandin compounds and routes of administration requires further investigation.

External cephalic version after previous cesarean section

Bruce L. Flamm, MD,[a] **Marc W. Fried, MD,**[b] **Neal M. Lonky, MD,**[c] **and Wendy Saurenman Giles, MD**[a]

Los Angeles, Riverside, and Anaheim, California

Approximately 100,000 cesarean sections are performed each year in the United States because of breech presentation. Numerous studies have shown that external cephalic version can eliminate the need for many of these operations. However, because of the fear of uterine rupture, these studies have generally excluded patients who have undergone previous cesarean section. To evaluate the validity of this exclusion policy, we studied patients with one or more previous cesarean sections and breech presentations near term. Version attempts were successful in 82% of 56 patients who had undergone a previous cesarean section. Sixty-five percent of the successful version patients went on to have vaginal birth after cesarean section. There were no serious maternal or fetal complications associated with the version attempts. We conclude that external cephalic version is a reasonable option in patients with prior low transverse cesarean section. (Am J Obstet Gynecol 1991;165:370-2.)

Key words: Vaginal birth after cesarean section, external cephalic version, breech, cesarean section

Many physicians agree that there is an increased risk of adverse perinatal outcome associated with vaginal breech delivery. This has led to an increasing use of cesarean section for infants in breech presentation. At some hospitals the proportion of breech infants delivered by cesarean section is approaching 100%.[1] Several recent studies have demonstrated that the majority of breech presentations can be successfully converted to the normal vertex presentation by the technique of external cephalic version.[2-4] However, these studies have generally excluded patients with prior cesarean section. The purpose of this report is to describe our experience with external cephalic version in 56 patients with prior cesarean sections.

Material and methods

The study was conducted between June 1, 1985, and June 1, 1990, at Kaiser Permanente Medical Centers in Los Angeles, Anaheim, and Riverside. Patients were eligible for inclusion in the study if they were at least 36 weeks' gestation, had a single fetus in breech presentation, and had a history of one or more cesarean sections. Exclusion criteria included ruptured membranes, labor, suspected intrauterine growth retardation, third-trimester bleeding, oligohydramnios, previous classical or vertical uterine scar, or suspicious fetal monitoring pattern on admission. The control group consisted of a series of 56 consecutive external cephalic version patients who met all the above inclusion and exclusion criteria but had no history of prior cesarean section.

The study protocol was approved by the regional institutional review board. Potential risks, benefits, and alternatives to the procedure were explained to each patient and written consent was obtained. Uterine rupture was defined as a separation involving all layers of the uterine wall. Ultrasonographic examination was performed to confirm the breech presentation, assess amniotic fluid volume, and rule out placenta previa. A nonstress test was then performed. At the discretion of the attending physician an initial version attempt was performed without tocolysis. If the version was not readily accomplished or if the fetus was not easily palpated, the patient was treated with either subcutaneous terbutaline sulfate (0.25 mg) or intravenous ritodrine hydrocloride (100 to 300 μg/min). The version techniques used have been previously described in detail.[2-4] The fetal heart rate was monitored during the procedure by real-time ultrasonography. Nonstress testing was repeated immediately after the procedure and again the next day.

Data were entered into a computerized data base. Analysis of data was performed with the χ^2 test or the Fisher exact probability test as appropriate. A p value ≤0.05 was considered to be statistically significant.

Results

Fifty-six patients with prior cesarean section fulfilled the inclusion criteria and underwent attempted external cephalic version. In 46 (82%) of these patients the fetus was successfully rotated to the vertex presentation. Table I compares the demographic characteristics of the study and control groups. With the exception of increased parity in the group with prior cesarean section, both groups were quite similar.

Table II summarizes the outcomes for both groups. Version attempts were more likely to be successful in the group with prior cesarean section (82% vs 61%, $p \leq 0.02$). This finding may simply reflect the increased parity in the group with prior cesarean section. The apparent trend toward increased reversion to breech in the group with prior cesarean section did not reach statistical significance (7% vs 2%, $p \leq 0.36$).

Table III summarizes the outcome of the group with prior cesarean section according to the indication for primary cesarean section. It was interesting to note that

41% of the prior cesarean sections had been performed because of breech presentation.

There were no uterine ruptures in the study or control groups at the time of version attempt or during subsequent trial of labor. Fetal heart rate abnormalities that necessitated cesarean section occurred during attempted external cephalic version in one patient in each group (1.8%). There were no major complications related to any of the version attempts. Four patients had two prior cesarean sections. Four patients had a history of a previous vaginal birth after cesarean section. Two patients had a history of successful external cephalic version in a prior pregnancy.

Comment

In a review article[5] it was concluded that external cephalic version is absolutely contraindicated in patients with previous uterine scars. There is little objective evidence to support this conclusion. The obvious concern is that the manipulations used during attempted version could rupture a previously scarred uterus. We did not find this to be the case. In this study there were no uterine ruptures in 56 version attempts. Because of the limited sample size, this study does not prove that the scarred uterus is at no increased risk of rupture during attempts at external cephalic version. This study indicates that the likelihood of successful external cephalic version is not lowered by the presence of a prior uterine scar.

The documented association of prior cesarean section and placenta previa accreta might generate some concern regarding the risks of external cephalic version in patients with prior cesarean section and anterior placental location. In this study, 39% of the group with prior cesarean section had anterior placental location and all underwent attempted external cephalic version without complications. Clearly, patients with ultrasonographic evidence of placenta previa would not be candidates for attempted external cephalic version regardless of the presence or absence of a prior uterine scar.

If a woman with a history of previous cesarean section presents near term with a breech presentation there are only three alternatives to external cephalic version:

1. Vaginal breech birth. Two recent studies[6, 7] have described good outcomes for vaginal birth after cesarean section with breech presentation in selected cases. However, this alternative will not be acceptable to the growing number of physicians who no longer perform any vaginal breech deliveries. National statistics indicate that the percentage of breech infants delivered by cesarean section rose from 14% in 1970 to 86% in 1986.[1]

2. Expectant management (hoping for spontaneous version). Because the rate of spontaneous version from breech to vertex after 37 weeks' gestation is only about 12%, the prudence of expectant management is questionable.[2]

3. Elective repeat cesarean section. It has been shown that cesarean delivery does not guarantee a good perinatal outcome for patients with breech presentation.[8] The mechanisms of breech delivery can present difficulties even through an abdominal incision.[9]

This study indicates that external cephalic version appears to be an acceptable alternative to elective repeat cesarean section or vaginal breech delivery for properly selected patients with breech presentation near term who have undergone prior cesarean section.

One-blade rotation of a persistent posterior vertex

Jorge O. Escamilla, MD, and Stephen J. Carlan, MD
Brooksville, Florida

Fifteen women in labor at term with no evidence of protraction or arrest disorder successfully underwent a single-blade rotation of the fetus from occipitoposterior to occipitoanterior position. There were no failures, no fetal injuries, and no significant maternal trauma. This method of forceps rotation appears to be a safe alternative to current methods of managing occipitoposterior positions. (Am J Obstet Gynecol 1991; 165:373-4.)

Key words: Forceps, malposition

Abnormalities of fetal positioning may be associated with dystocia. Therefore a method to assist rotation to the occipitoanterior position may be helpful. This article describes a technique of single-blade rotation that is similar to a method first reported in 1954.

Material and methods

Fifteen patients in spontaneous labor at term with no evidence of protraction or arrest disorder underwent rotation from occipitoposterior or oblique to occipitoanterior with a single pseudofenestrated Tucker-McLane blade. All patients met the standard prerequisites for forceps operation including appropriate application and indication, empty bladder, full cervical dilatation, ruptured membranes, and operator certainty of fetal position and station. All stations at the time of rotation were +3 or +2 with the exception of one patient at +1. The clinical characteristics of the patients and newborns are shown in Table I, and the method of application and rotation is illustrated in Figs. 1 to 4.

Table I. Clinical characteristics ($N = 15$)

Gravidity	3.06 ± 2.41
Parity	1.26 ± 1.44

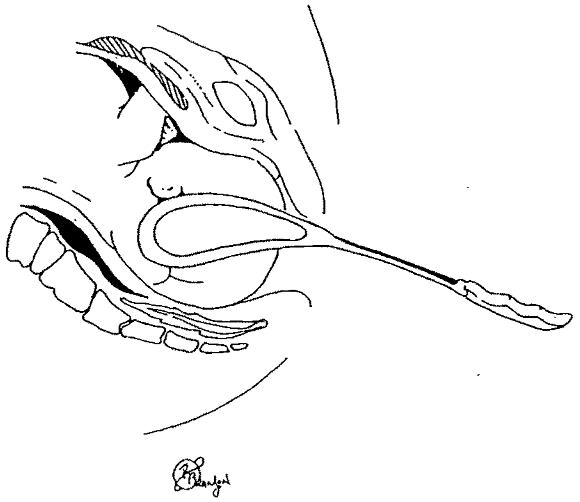

Fig. 1. Blade being introduced upside down to opposite side of maternal pelvis.

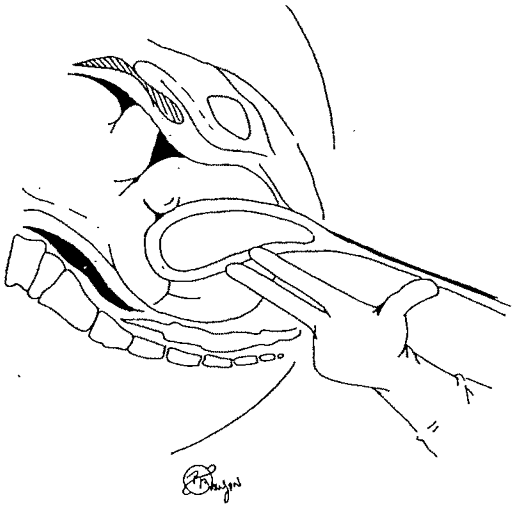

Fig. 2. With second and third fingers, gently rotate up and around under pubic symphysis and "wander" blade over ear (see Fig. 3). Cephalic curve of blade holds malar imminence and convex parietal bone, resulting in rotation of head with blade. If head does not easily rotate, effort is terminated. Care is taken not to angle edge of blade into fetal head or maternal tissue.

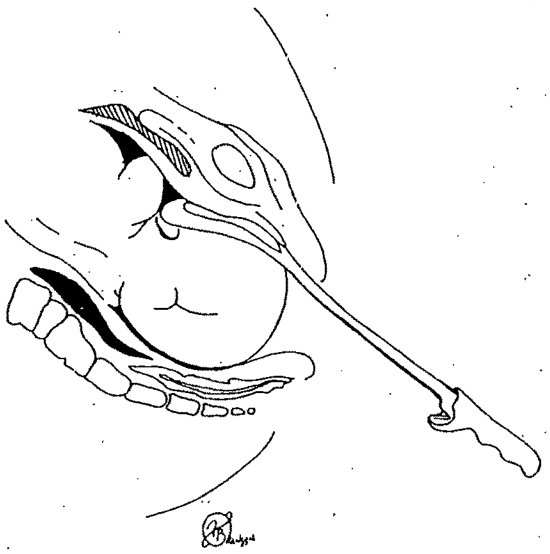

Fig. 3. Blade under symphysis. Cephalic pole is rotating.

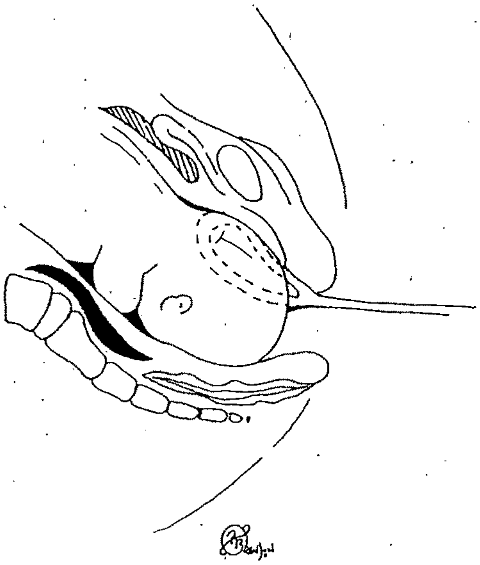

Fig. 4. Presenting part has rotated out of occipitoposterior position. After successful rotation, blade is held in place through several contractions to ensure that fetus does not revert back to occipitoposterior position.

Results

Spontaneous vaginal delivery occurred in 12 patients, and outlet forceps were required in three patients whose fetal heart rate tracing became nonreassuring after the rotation. No fetal injuries or sequelae were noted. Maternal injuries included two fourth-degree lacerations and one slight extension of the episiotomy. All infants were discharged from the hospital with their mothers by 72 hours of life.

Comment

Several management options for occipitoposterior or oblique position are possible. The simplest nonoperative options are watchful expectancy and maternal repositioning. Operative options include manual rotation, delivery of the infant in an occipitoposterior position by forceps or vacuum, or forceps rotation. A number of variations of the two-blade forceps rotation method exist. However, because of the large amount of blade manipulation that is required during these rotations, great skill is necessary to avoid significant maternal-fetal trauma. In an attempt to reduce the trauma associated with forceps rotations, two methods of single-blade rotation were introduced in the 1950s. Maughan[1] used a single fenestrated blade to catch the most anterior fetal ear between the fenestrations and rotate the head out of the posterior position. The second method is the Merchan technique[2]; it is similar to the technique described in this report. With this method the risk of tissue injury should be decreased because blade manipulation is minimal. In summary, in the fetus with an occipitoposterior or oblique position, with no contraindications for forceps operation and a clear indication for expedited delivery, the single-blade rotation appears to be a safe and simple option.

Comparative efficacy of clindamycin versus erythromycin in eradication of antenatal *Chlamydia trachomatis*

Lindsay S. Alger, MD,[a] and Judith C. Lovchik, PhD[b]
Baltimore, Maryland

Antenatal *Chlamydia trachomatis* infections are associated with both maternal and neonatal morbidity. Erythromycin, the only drug recommended for treatment during pregnancy, is often poorly tolerated, thus preventing successful cure. We have done a prospective, randomized, double-blind, placebo-controlled trial to compare the efficacy of clindamycin with that of erythromycin base in eradication of antenatal chlamydia. A total of 126 patients with documented cervical infection were enrolled before 24 weeks' gestation to receive clindamycin (450 mg), erythromycin (333 mg), or placebo orally four times daily for 14 days. Partners received doxycycline, 100 mg, twice daily for 7 days. Both clindamycin and erythromycin were effective agents with cure rates of 92.7% and 83.8%, respectively. Erythromycin therapy was associated with significantly more gastrointestinal complaints than was placebo therapy (23.1% (9/39) vs. 2.4% (1/41), $p < 0.02$) whereas clindamycin was not. Patients who experienced side effects were more likely to be poorly compliant ($p < 0.03$) and patients with moderate-to-good compliance were more likely to be cured than were women who were poorly compliant ($p < 0.002$). Results of test of cure cultures performed immediately on completion of therapy did not differ significantly from those taken 4 weeks later. (AM J OBSTET GYNECOL 1991;165:375-81.)

Key words: *Chlamydia trachomatis,* antenatal antibiotic therapy, clindamycin

Chlamydia trachomatis is the most prevalent sexually transmitted pathogen in many obstetric populations. Although obtaining routine antenatal samples for *C. trachomatis* screening has not been standard in this country, there are several reasons to advocate adoption of this policy. In any given population, *C. trachomatis* is encountered three to five times more frequently than *Neisseria gonorrhoeae*, a pathogen routinely screened for in most obstetric clinics. Recent advances in diagnostic methods have made *C. trachomatis* diagnosis readily available to physicians. Left untreated, a woman may: (1) transmit the organism to her offspring at delivery (60% to 70% of neonates delivered through an infected birth canal will become infected, potentially developing conjunctivitis, pneumonia, otitis media, or gastroenteritis); (2) undergo development of endometritis-salpingitis postpartum (upper genital tract disease will develop in approximately 22% to 34% of women with cervical infection within 6 weeks of delivery[1, 2]); (3) experience an adverse obstetric outcome (in a previous case-control study[3] we found that cervical infection with *C. trachomatis* was significantly associated with preterm premature rupture of the membranes [PROM]); and (4) serve as a vector for continued spread of the disease in the community.

Currently, the only drug recommended for treatment of chlamydial infections during pregnancy is erythromycin. However, some patients are unable to complete a therapeutic course because of undesirable side effects, specifically nausea and gastrointestinal distress. Pregnancy predisposes the patient to development of these complaints, and compliance is frequently poor. In hospitalized patients unable to take oral medications, erythromycin is poorly tolerated when administered intravenously because it is irritating to veins. Alternative therapy with equivalent efficacy but fewer side effects is needed. Preliminary studies with clindamycin in nonpregnant populations suggest that this medication is well tolerated and efficacious.[4, 5] This study was undertaken to determine the comparative efficacy of clindamycin and erythromycin in eradication of *C. trachomatis* from the lower genital tract in pregnant women and whether clindamycin is better tolerated and, hence, promotes patient compliance and cure rates superior to erythromycin.

Material and methods

After approval from our institutional review board and the Federal Food and Drug Administration, a randomized, double-blind, placebo-controlled trial was conducted, enrolling patients from the University of Maryland Hospital Obstetrical Clinic between October 1985 and April 1988. Women with a cervical specimen

*Term plus preterm deliveries.

culture-positive for *C. trachomatis* before 24 weeks' gestation were eligible with the following exclusions: sensitivity to study medication; significantly impaired hepatic function; persistent gastrointestinal symptoms or history of colitis; antibiotic therapy after screening and before enrollment; or current treatment with insulin, steroids, carbamazepine, or warfarin.

After informed consent was obtained eligible participants between 16 and 24 weeks' gestation were randomly assigned to one of three treatment groups: (1) erythromycin base tablets (333 mg) and clindamycin placebo, (2) clindamycin capsules (450 mg) and erythromycin placebo, or (3) erythromycin placebo and clindamycin placebo. Group 3, the placebo-control group, resulted from the participation of these patients in a separate investigation to determine whether antenatal treatment of chlamydia improves pregnancy outcome, which required a placebo arm. All patients understood the risks associated with untreated infection. All medications were administered orally, four times a day for 14 days. Partners received doxycycline (100 mg) twice daily for 7 days. Medications were dispensed in blister packs with each dose packaged sequentially in an individual cell, permitting accurate determination of the specific number and timing of missed doses.

Participants were screened for *N. gonorrhoeae* before enrollment and, when indicated, treated with intramuscular aqueous procaine penicillin G and oral probenecid according to guidelines of the Centers for Disease Control. Patients were proscribed for the duration of the pregnancy from receiving additional antibiotics without the approval of the investigator. Infectious conditions that required therapy were treated with antibiotics that do not provide *C. trachomatis* coverage (e.g., nitrofurantoin for urinary tract infections). Women who received antibiotics that might influence *C. trachomatis* recovery were withdrawn from the study.

The initial test of cure for *C. trachomatis* was performed at completion of therapy, 14 days after the first dose of study medication. A second test of cure was obtained approximately 4 weeks later. On admission to the Labor and Delivery Suite for labor or ruptured membranes (whether preterm or term), a final specimen was submitted for *C. trachomatis* culture. All specimens were obtained from the endocervical canal with plastic-handled, cotton-tipped swabs after the ectocervix had been cleared of secretions. Specimens for *C. trachomatis* isolation were placed immediately in transport media and processed within 12 hours. They were inoculated into cycloheximide-treated McCoy cells in shell vial monolayers, incubated for 40 hours, fixed with methanol and stained with fluorescein-conjugated monoclonal antibody to *C. trachomatis* (Kallestad Laboratories, Austin, Tex.). Inclusions were detected by epifluorescence microscopy.

To prevent inadvertent retreatment outside of the study protocol, culture results were not available to members of the clinic medical staff but were reported by study number only to the investigators. All patients with positive culture results at delivery were treated immediately post partum with doxycycline in conventional doses as were their present partners. All infants were followed-up by the pediatrics staff for 3 months.

Patients returned their used pill packs along with those of their partners at the first test of cure. Compliance was assessed as either good, moderate, or poor. Patients who missed four or fewer of the 56 total doses were defined as demonstrating good compliance. Patients who completed at least 28 doses (equivalent to a minimum of 1 week of therapy) exhibited moderate compliance, whereas missing more than 28 doses constituted poor compliance. Because specimens from partners were generally unavailable to document partner cure, it was presumed that partners had been successfully treated if the returned blister packs indicated that no more than two doses had been missed.

Statistical analysis for categoric data was performed with χ^2 tests and by Fisher's exact tests when categories contained fewer than five subjects.

Results

A total of 135 eligible patients were enrolled in the study. Of these, delivery outcome data were available for 126; nine patients were delivered of infants elsewhere and were lost to follow up. Forty-two women received clindamycin, 40 received erythromycin, and 44 received placebo. Demographic characteristics of the patients in each treatment group are shown in Table I. There were no significant differences between the groups at the time of enrollment with regard to any of these parameters, and there were no differences in the number of sexual partners at enrollment or in the num-

ber of untreated sexual partners between treatment and delivery.

Both clindamycin and erythromycin were effective agents in the treatment of antenatal *C. trachomatis* infection. Table II lists the failure rates for each of the treatment regimens at the first and second test of cure and at the time of delivery. With cure defined as only negative cultures at the first or second test of cure, 92.7% of patients who received clindamycin and 83.8% of patients who received erythromycin were cured as shown in Table III. Although therapy failed in twice as many patients with erythromycin as it did with clindamycin, this difference was not significant. For those patients who completed at least 28 doses of medication, 94.3% of patients who received clindamycin and 93.3% of patients who received erythromycin were cured.

Eighty-five percent of the treatment population never had a subsequent positive culture throughout the study. In particular, 88.1% of the patients who received clindamycin and 82.5% of erythromycin-treated patients remained disease-free. Of patients who completed at least 28 doses of medication, 88.9% of patients receiving clindamycin and 87.9% of patients receiving erythromycin had no recurrence of *C. trachomatis* during the entire pregnancy.

Overall, among patients who received antibiotic therapy, the first and second test of cure culture results were concordant in 96%. Of the 67 patients who received antibiotics and were culture-negative at the first test of cure, 61 (91%) had no positive cultures for the remainder of the pregnancy. Of the six patients who were subsequently culture-positive, two were already positive 4 weeks after the completion of therapy; one, if not both, of these women had never been cured initially of her infection inasmuch as she took only one dose of the study medication. In one of the four remaining patients there was documented poor partner compliance. Partner compliance data was unavailable for two women. Thus even if we assume these two men were compliant, of those patients who completed therapy and were initially cured, no more than four (6%) had subsequent unexplained recurrences during the remainder of pregnancy.

Table III. Treatment efficacy

Antibiotic	*No.*	*% Cured patients*	*% Cured of patients taking ≥28 doses*
Clindamycin	41	92.7	94.3
Erythromycin	37	83.8	93.3
Placebo	44	22.7	25.0

Nine of the women who received placebo (20%) had no subsequent positive cultures for the remainder of pregnancy, eight of these nine having three successive negative cultures. Careful review of these patients' charts confirmed that (1) all patients were initially culture-positive, (2) all denied taking any antibiotics other than those administered through the study, either before or subsequent to enrollment, and (3) no mention of additional therapy was documented in the chart. Negative cultures from placebo-treated patients were most common at delivery. Indeed, patients who received placebo were twice as likely to be culture-negative at the time of delivery as earlier in pregnancy. Of 40 women in the placebo group for whom culture results were available, 23 (58%) had negative cultures at delivery.

No major side effects were encountered in either antibiotic treatment group; only one patient had therapy discontinued by the investigators. An extensive, pruritic rash developed in this patient that, subsequent to discontinuation of the study medication (erythromycin), was diagnosed as varicella. Two patients who received clindamycin reported development of a rash but both patients completed the entire course of therapy and no rash was apparent at the first test of cure visit. One patient died of toxic shock syndrome 11 days after she was delivered of an infant at another hospital. More than 4 months had elapsed since the partial completion of her course of clindamycin within the study protocol. Overall, 85% of patients who received clindamycin, 77% of patients who received erythromycin, and 98% of patients who received placebo experienced no side effects.

Erythromycin therapy was associated with significantly more gastrointestinal complaints than was placebo therapy ($p < 0.02$). Vomiting, diarrhea, or abdom-

Table IV. Side effects versus compliance

Compliance	No.	Experienced side effects	
		No.	%
Good			
0-4 doses missed	70	8	11.4
Moderate			
5-28 doses missed	39	4	10.3
Poor			
>28 doses missed	9	4	44.4*

*$p < 0.03$, moderate to good compliance versus poor compliance.

inal pain developed in nine of 39 (23.1%) women compared with one placebo-treated patient. In three instances, therapy failure was directly linked to discontinuation of the study medication by the participant because of side effects. In contrast, 10% (4/40) of patients who received clindamycin complained of gastrointestinal side effects, but all these women were able to complete a sufficient number of doses to cure the infections. Only patients who received erythromycin complained of significant abdominal pain or cramping (4/39). (One patient complained of stomach pain after the first dose of clindamycin.) Diarrhea, defined as more than three loose bowel movements in a 24-hour period, developed in two patients while taking erythromycin. One patient who received clindamycin complained of diarrhea and discontinued therapy without discussing this with the investigator. *Candida vaginitis* was an infrequent finding in all three groups and was not temporally related to treatment.

Patient compliance data were available for 118 of the 126 women. Overall, compliance in this indigent, clinic population was quite good. The great majority (92.4%) of women completed at least 28 doses of therapy; 59% did not miss more than four doses. The development of side effects and patient compliance were interrelated as shown in Table IV. Patients who experienced side effects were more likely to be poorly compliant ($p < 0.03$). In the erythromycin-treatment group, three of the four patients (75%) with poor compliance for whom side effects data were available, experienced side effects compared with 25.0% (4/16) of patients with moderate compliance and 11.8% (2/17) with good compliance. Women treated with placebo were the most compliant whereas patients who received erythromycin were the least compliant, although these differences were not significant ($p = 0.06$) (Fig. 1).

Patient compliance was also related to cure (Table V). Women with moderate-to-good compliance were more likely to be cured than women who were poorly compliant ($p < 0.002$). The difference in cure rates between patients with moderate compliance and those with good compliance was not significant. Patients who completed at least 28 doses of therapy were as likely to be cured as those who completed 52 doses of therapy.

Compliance data were available for 96 of the partners; 89.6% were compliant, but it is possible that many of the partners for whom compliance data were unavailable because of failure to return the pill packs were noncompliant. Several patients did not resume sexual activity with a noncompliant partner after treatment.

Partner compliance was also significantly associated with cure. Ten percent of antibiotic-treated subjects with compliant partners had a subsequent positive chlamydia culture compared with 50% of subjects whose partner compliance was poor and 22% whose partner compliance was unavailable ($p < 0.03$). Even in placebo-treated patients, a partner effect on cure was suggested. In the nine patients with only negative cultures after treatment, partners missed no doses of medication or the patient denied sexual contact after treatment. In contrast, in 11 of 35 (31.4%) placebo-treated patients in whom at least one subsequent culture was positive, posttreatment sexual contact with a noncompliant partner could not be excluded.

Comment

Each year more than 4 million cases of chlamydial infection occur in the United States and 155,000 infants are born to mothers with genital chlamydia.[6] Chlamydial conjunctivitis will develop in approximately 30% to 40% of exposed infants, whereas pneumonia occurs in 10% to 20%.[7] Several investigators have noted an association between maternal cervical infection with *C. trachomatis* and preterm delivery.[3, 8-10] Currently, the only drug recommended for treatment of chlamydial infections during pregnancy is erythromycin.

Erythromycin has demonstrated efficacy in vivo in the treatment of chlamydial cervicitis with reported cures varying between 76% and 100% in nonpregnant populations.[11-13] Little information is available on doses or efficacy in the pregnant patient. Schachter et al.[14] have shown that antenatal treatment with erythromycin can successfully eradicate *C. trachomatis* from the maternal genital tract during pregnancy. Unfortunately, at the recommended dose of 500 mg, orally, four times daily, a significant number of patients experience undesirable gastrointestinal side effects and are unable to complete a therapeutic course. Robson et al.[15] noted that gastrointestinal complaints, including nausea, vomiting, and abdominal pain, occurred in 10 of 19 nonpregnant patients on this regimen, whereas Bowie et al.[16] had to discontinue this arm of their study when among the first 13 patients, major side effects developed in five patients. These side effects necessitated either stoppage of treatment or reduction of the dose by at least half. Reduction of the dose to 250 mg

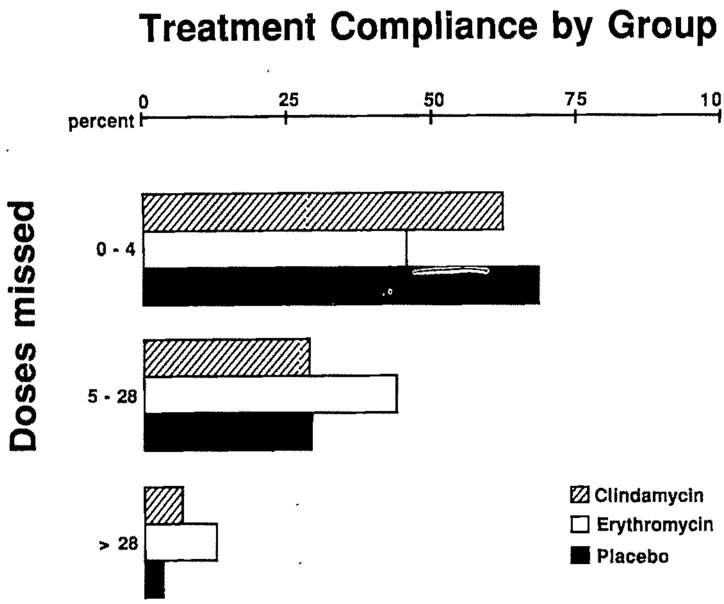

Fig. 1. Percentage of patients in each treatment group with good, moderate, or poor compliance. Similar compliance was exhibited by placebo and clindamycin groups.

orally, four times daily as recommended in the guidelines of the Centers for Disease Control, may not eliminate these side effects and requires extention of the course of therapy for an additional week, which is burdensome to many patients. In addition, relative resistance of *C. trachomatis* to erythromycin has been reported.[17]

Several antibiotics have demonstrated efficacy in the treatment of chlamydial cervicitis in the nonpregnant patient. In addition to erythromycin, tetracycline,[18] doxycycline,[19] sulfisoxazole,[16] and trimethoprim-sulfamethoxazole[18] are effective but are generally considered contraindicated during pregnancy. Even in nonpregnant patients trimethoprim-sulfamethoxazole has been associated with neurologic side effects in 36% of treated women.[18] Clindamycin has been shown to have both in vitro[20] and in vivo[21] activity against strains of *C. trachomatis*. The minimal inhibitory concentration of clindamycin is tenfold greater than that of erythromycin but serum levels remain above the minimal inhibitory concentration for almost 4 hours after a single 450 mg oral dose of clindamycin. Although there is no information on the use of clindamycin to eradicate *C. trachomatis* during pregnancy, there have been no reports of adverse fetal or maternal outcome when clindamycin has been used to treat other conditions during pregnancy.

Our results demonstrate that clindamycin is an effective and well-tolerated antimicrobial agent for the treatment of antenatal cervical chlamydia infection. More than 94% of patients who completed at least 28 doses of therapy were cured. One week of treatment appears to be sufficient and there does not appear to be any advantage to extending therapy beyond 28 doses. When compared with erythromycin, clindamycin was equivalent in efficacy. Although twice as many patients remained infected after treatment with erythromycin as did after receiving clindamycin, this was not statistically significant but did appear to be related to patient compliance. Patients who took similar numbers of doses had similar cure rates with either drug. A larger study would be necessary to exclude the possibility of β-error and the superiority of clindamycin.

With the use of a 333 mg preparation of erythromycin we found cure rates within the range previously reported in the literature for a variety of dosing regimens. However, a significant number (23.1%) of women still experienced gastrointestinal side effects,

Table V. Cure versus compliance in antibiotic-treated patients

*$p < 0.00004$, moderate-to-good compliance versus poor compliance.

although not as frequently as reported by other investigators with the 500 mg dose. Vomiting, diarrhea, or abdominal cramps developed in these patients and three of them completed less than 1 week of therapy because of these side effects. Clindamycin was better tolerated and did not require discontinuation of therapy. Rash, the only other side effect, was uncommon and not serious. Pseudomembranous colitis did not occur in the study population.

Not only were both medications effective, but 85% of the study participants did not have a documented recurrence of *C. trachomatis* for the remainder of pregnancy. Most of those initially culture-negative after treatment (91%) had no subsequent positive cultures. This is in contrast with the group B streptococcus, which although reported to be associated with preterm delivery cannot be eliminated from the vagina for more than a few weeks in most cases, making it impractical to treat early in pregnancy as a means to reduce neonatal complications. Patients in this study were not treated before 16 weeks' gestation to avoid the period of fetal organogenesis and greatest incidence of pregnancy-related nausea. However, all patients were treated before 24 weeks' gestation which might be early enough to reduce the incidence of *C. trachomatis*-related prematurity. Additional studies are necessary to establish whether antenatal treatment of *C. trachomatis* will reduce adverse pregnancy outcome.

A surprising number of patients in the placebo group were also "cured" of infections during pregnancy. Eight patients (18%) had three successive negative cultures after the initial positive screening culture, and no evidence of any other form of treatment could be found. It is unlikely that all eight patients had three successive false-negative cultures and therefore, as with group B streptococci and many other pathogens, it may be possible for host defenses alone to eliminate the infection antepartum. This may be particularly likely if there is no further sexual activity with an infected partner.

It has been recommended that test of cure cultures for *C. trachomatis* be obtained 3 to 4 weeks after completion of therapy. The rationale is that because of the extraordinarily long replication cycle of *C. trachomatis*, a long interval between end of therapy and test of cure is necessary to differentiate between true eradication of the organism and mere suppression. However, we found that for 96% of women results of the first test of cure obtained immediately after the completion of therapy were concordant with results of the second test of cure. Although a negative test of cure followed by a positive test of cure may represent evidence of *C. trachomatis* suppression it may equally represent an example of reinfection with the organism. Because patients with a negative second test of cure culture may also become reinfected (although this occurred in only 2.8% of our study population) it apppears that an acceptable and more practical alternative is to obtain a test of cure culture at the first clinic visit after completion of therapy and to obtain a subsequent screening culture later in pregnancy.

Whereas there was no difference in accuracy between the first and second test of cure for women who received placebo, cultures taken in the delivery suite once the patient was in labor were twice as likely to yield negative results as were antepartum cultures. It is possible that these cases represent spontaneous cures; however, it is more likely that adequate sampling is more difficult during active labor when the cervix may be significantly effaced, the fetal head well-applied to the columnar epithelium of the endocervical canal, the membranes ruptured, and when blood, mucus and intraamniotic debris may contaminate the specimen. Studies in which cultures are performed only at delivery may therefore significantly underestimate the role of *C. trachomatis* in peripartum events. In addition to being less accurate, *C. trachomatis* cultures obtained during labor rarely provide results within a time frame that permits the prevention of vertical transmission.

Successful treatment requires patient and partner compliance in addition to an effective drug. Compliance, in turn, is dependent on patient education as to the importance of treatment and the method of treatment, the ready availability of the treatment, and reduction of any adverse consequences related to treatment. The successful results achieved in this study are a result of such a three-pronged approach. Patients were anxious to rid themselves of an organism that was a health hazard to themselves and their infants. They understood that this was possible only if their partners were cured as well. Most important, medication for the patient and her partner was supplied directly to the patient. Requiring the partner to present to a clinic for diagnosis and treatment is a significant impediment to the successful treatment of women. In our clinics this approach has been associated with a 40% failure rate, more than double that of this study.

We conclude that clindamycin is an effective alternative to standard treatment regimens for chlamydia during pregnancy. Clindamycin appears to be particularly well tolerated by patients and may be associated with better compliance than erythromycin. For patients unable to tolerate erythromycin, clindamycin is an excellent alternative, but because of its greater cost larger studies are necessary to confirm improved cure rates before routine use of clindamycin can be advocated.

Enhanced sensitization after cordocentesis in a rhesus-isoimmunized pregnancy

Scott N. MacGregor, DO, Richard K. Silver, MD, and John S. Sholl, MD
Evanston, Illinois

It has been suggested that the optical density at 450 nm may be an unreliable predictor of the severity of fetal anemia in the midtrimester of pregnancy; therefore fetal blood sampling, rather than amniotic fluid evaluation, should be performed in all isoimmunized pregnancies with elevated maternal antibody titers in the midtrimester. Potential complications of such an approach are discussed and an alternative plan of management is offered. (AM J OBSTET GYNECOL 1991;165:382-3.)

Key words: Rh isoimmunization, cordocentesis, optical density at 450 nm

Amniotic fluid assessment of the optical density at 450 nm (ΔOD_{450}) has been used as an indicator of the severity of fetal anemia secondary to red blood cell isoimmunization. Recently, Nicolaides et al.[1] have suggested that the ΔOD_{450} may be an unreliable predictor of the severity of fetal anemia in the midtrimester of pregnancy. In contrast, fetal blood sampling by cordocentesis allows direct access to the fetal circulation and precise evaluation of the fetal hematocrit. Therefore they suggested that fetal blood sampling, rather than amniotic fluid evaluation, should be performed in all isoimmunized pregnancies with elevated maternal antibody titers in the midtrimester. There are some controversial issues associated with this approach. For example, the fetus whose antigen status is the same as its mother and who is not at risk for hemolytic anemia would be exposed to possible complications associated with cordocentesis, such as bleeding, cord hematoma, umbilical artery spasm, infection, and death. The following case report addresses another hazard of fetal blood sampling, namely, that it may introduce fetal red blood cells into the maternal circulation and thereby increase maternal antibody production and the severity of the isoimmunization.

Case report

A 25-year-old woman, gravida 4, para 2-1-0-3, had known anti-D isoimmunization. Her second pregnancy resulted in delivery of an Rh-positive infant who required exchange transfusion after delivery. In her subsequent pregnancy, serial amniocentesis and amniotic fluid ΔOD_{450} measurements were performed, the results of which remained reassuring. At delivery, the infant was Rh negative, indicating that the patient's husband was heterozygous for the D antigen. During her fourth pregnancy, the maternal anti-D antibody titer was 1:8 at 24 weeks' gestation, when she was referred to our institution. The patient was offered the option of either amniocentesis and amniotic fluid ΔOD_{450} measurement or cordocentesis for determination of fetal blood type and hematocrit. The patient was informed that cordocentesis may have a higher risk of complications than amniocentesis has; however, it offered the potential for a single procedure if the fetus was Rh negative, whereas serial amniocentesis would be required even if initial results were reassuring. Additionally, cordocentesis could more precisely determine the need for therapy if the fetus was Rh positive. The patient chose to have fetal blood sampling performed because of the potential for a single procedure.

At 25 weeks 3 days of gestation cordocentesis was performed under ultrasonographic guidance. A 22-gauge, 5-inch spinal needle was introduced into the umbilical vein at its placental insertion, traversing the anterior placenta. A single uterine and cord puncture was required for sampling, and the duration of the procedure was <10 minutes. The fetus was Rh positive with positive results of direct Coombs testing at an antibody titer of 1:4. The fetal hematocrit was 31%, and transfusion was not performed. Kleihauer-Betke testing performed on the maternal blood sample after the procedure was negative for fetal red blood cells.

Weekly ultrasonographic examination and maternal antibody evaluation were performed with plans to repeat fetal blood sampling 2 to 4 weeks after the initial procedure. The maternal antibody titer increased to 1:4096 3 weeks after the initial procedure. Ascites and scalp edema were observed on ultrasonographic examination. Repeat fetal blood sampling was performed, and the fetal hematocrit was 12% and the fetal antibody titer was 1:512. Fifty milliliters of irradiated, cytomegalovirus-negative, type O, Rh-negative packed red blood cells were transfused into the umbilical vein, increasing the fetal hematocrit to 38%. Sampling and transfusion were accomplished through a single cord

puncture and the duration of the procedure was approximately 25 minutes. After the procedure, nonremediable fetal bradycardia occurred, which prompted an emergency cesarean section. A 1505 gm male infant was delivered with an umbilical artery pH of 7.34 and a cord hematocrit of 36%. An umbilical cord hematoma was observed at the site of cord puncture and was presumed to be the cause of the bradycardia.

The infant required a single exchange transfusion during the first 48 hours of life and received three additional simple transfusions. Phototherapy for hyperbilirubinemia was required for 7 days. The infant had intermittent mechanical ventilation for the first 24 hours and oxygen therapy for 3 days because of mild respiratory distress syndrome. He was eventually discharged weighing 2100 gm and doing well on day 40 of life.

Comment

Cordocentesis has improved both evaluation and therapy in fetuses with severe red blood cell isoimmunization. Complications associated with this procedure, such as premature rupture of membranes, premature labor, placental bleeding, and infection, are similar to those observed with amniocentesis. Complications involving the umbilical cord, such as hematoma formation, bleeding, and vasospasm, are unique to this procedure. Additionally, fetomaternal bleeding may occur. Passage of fetal red blood cells into the maternal circulation may stimulate maternal antibody production in isoimmunized pregnancies, potentially increasing the severity of continuing fetal hemolytic anemia. In the case presented, it is not possible to be certain whether fetomaternal bleeding during the initial fetal blood sampling stimulated increased maternal antibody production. However, the maternal antibody titer rise from 1:8 to 1:4096 and the development of severe anemia and hydrops in 3 weeks were dramatic and atypical events.

The amniotic fluid values of ΔOD_{450} are generally a reliable indicator of the severity of fetal isoimmunization during the third trimester of pregnancy. Nicolaides et al.[1] have suggested that amniotic fluid ΔOD_{450} correlated poorly with fetal hematocrit in the second trimester, such that the only reliable method to evaluate the severity of fetal isoimmunization in the second trimester was the direct measurement of fetal hemoglobin or hematocrit. However, analysis of their data shows that all of the severely anemic (hemoglobin, <6 gm/dl) fetuses had ΔOD_{450} values >0.1 in the second trimester. Evaluation of amniotic fluid ΔOD_{450} has shown that measurements rise between 14 and 20 weeks' gestation, plateau between 20 and 26 weeks' gestation, and then trend downward during the third trimester.[2] In addition, the 95th percentile confidence limit of ΔOD_{450} values during the second trimester is only slightly >0.1. Therefore the majority of amniotic fluid sampled during the second trimester would be expected to have ΔOD_{450} values <0.1, which could be used as a cutoff value to determine whether to proceed to cordocentesis.

This case report suggests that there is potential risk of increased maternal antibody production to be considered when fetal hematocrit assessment by cordocentesis is contemplated rather than ΔOD_{450} assessment by amniocentesis in pregnancies complicated by isoimmunization in the second trimester. In the pregnancy with paternal heterozygosity, cordocentesis to determine fetal blood type may offer the opportunity for a single procedure. However, second-trimester amniocentesis for ΔOD_{450} should continue to be considered in the management of these fetuses. Although fetomaternal hemorrhage may occur during amniocentesis, it is probably more likely to occur during cordocentesis with invasion of the fetal circulation. We would propose a management scheme in the second trimester where only those fetuses with ΔOD_{450} values >0.1 undergo fetal blood sampling, thereby reducing the number of cases requiring fetal blood sampling but still indentifying severely sensitized fetuses. Enhanced sensitization after cordocentesis, as well as cord complications, would likely be avoided in the majority of isoimmunized pregnancies.

Congenital hydronephrosis: Correlation of fetal ultrasonographic findings with infant outcome

Jane E. Corteville, MD, Diana L. Gray, MD, and James P. Crane, MD
St. Louis, Missouri

Although congenital hydronephrosis is a common fetal disorder, ultrasonographic criteria for prenatal diagnosis remain poorly defined. In this study prenatal ultrasonographic findings were correlated with postnatal outcome in 63 fetuses with suspected hydronephrosis. Prenatal ultrasonographic measurements included length, anteroposterior diameter, and transverse diameter of the kidney and renal pelvis, as well as dorsal renal parenchymal thickness. In 45 of the 63 fetuses, hydronephrosis was confirmed postnatally. These infants were divided into two groups on the basis of renal status: (1) abnormal renal function and/or surgery required ($n = 31$) and (2) normal renal function with no surgery required ($n = 14$). The anteroposterior diameter of the renal pelvis was the simplest and most sensitive technique for prenatal diagnosis of congenital hydronephrosis, allowing identification of 100% of cases. Postnatal follow-up studies are warranted if an anteroposterior pelvic diameter is ≥4 mm before 33 weeks or ≥7 mm after 33 weeks. (AM J OBSTET GYNECOL 1991;165:384-8.)

Key words: Congenital hydronephrosis, prenatal diagnosis, ultrasonography, infant outcome

Congenital hydronephrosis is a commonly encountered birth defect, occurring with a frequency of 1 in every 330 infants (unpublished data). Clinical presentation is variable and may include a palpable abdominal mass, intermittent pain, vomiting, failure to thrive, or urinary tract infection. Surgical correction of congenital hydronephrosis within 6 to 12 months of birth is typically associated with good outcome whereas delayed diagnosis carries an increased risk of renal impairment.[1, 2] Unfortunately, diagnosis on clinical grounds alone is often delayed with <25% of cases detected by age 1 and only 55% by age 5.[3] Prenatal ultrasonography affords the opportunity for early recognition and treatment of congenital hydronephrosis with hopeful preservation of renal function.

While several ultrasonographic criteria have been suggested for prenatal diagnosis of congenital hydronephrosis,[4-8] few are based on long-term infant outcome and assessment of renal function. The purpose of this investigation was to assess the relative accuracy of these ultrasonographic techniques in the same population to determine the best predictor(s) of renal compromise and/or the need for surgical intervention after birth.

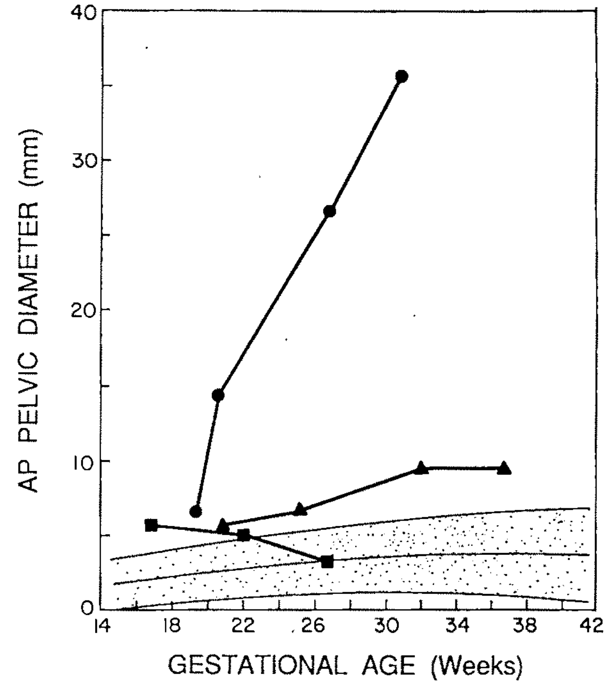

Fig. 2. Natural history of congenital hydronephrosis. Case 39 (●) was classified as having progessive lesion. Fetus in case 32 (▲) had stable hydronephrosis with serial anteroposterior pelvic diameters that paralleled normal reference range. In case 55 (■) spontaneous resolution was observed.

graphic studies were performed for an average of 3.9 per fetus. The examinations were divided into three gestational age time frames (14 to 23.9, 24 to 32.9, and 33 to 42 weeks) with only a single examination per fetus included in each. The following renal measurements were obtained at each ultrasonographic examination: (1) kidney length, transverse diameter, and anteroposterior diameter; (2) renal pelvis length, transverse diameter, and anteroposterior diameter; (3) maximal renal parenchymal thickness.

Kidney and renal pelvis lengths were measured in a coronal plane whereas transverse and anteroposterior dimensions were measured in an axial plane through the fetal abdomen. Renal parenchymal thickness was measured along the dorsum of the kidney when viewed in an axial plane (Fig. 1).

Infant outcome was collected by chart review. The mean duration of follow-up was 20 months with a range of 1 to 71 months. Primary end points included: (1) the accuracy of each ultrasonographic parameter in diagnosing congenital hydronephrosis and (2) the ability of ultrasonography to predict adverse outcome as determined by the presence of renal compromise and/or need for surgical intervention. Postnatal congenital hydronephrosis was confirmed by ultrasonography, intravenous pyelography, or renal scintigraphy. Criteria for defining renal compromise included any of the following findings: (1) serum creatinine level >0.7 mg/dl more than 7 days after delivery; (2) cortical atrophy identified by intravenous pyelography, postnatal sonogram, or renal scintillation scan; (3) differential excretion >20% on renal scintillation scan, or (4) significant urinary tract infection (more than two in female infants and more than one in male infants).

To evaluate which fetal renal dimensions best predict outcome, the following ultrasonographic parameters were examined: (1) anteroposterior diameter of the renal pelvis, (2) ratio of anteroposterior diameters of renal pelvis to kidney, (3) ratio of transverse diameters of the renal pelvis to kidney, (4) kidney circumference/abdominal circumference ratio, and (5) maximal renal parenchymal thickness.

Multiple thresholds were analyzed for each of these parameters and correlated with infant outcome. The goal was to choose the threshold with the highest sensitivity for predicting congenital hydronephrosis to minimize the chance of missing a clinically significant lesion. False-positive rates for each threshold also were determined.

Secondary analyses included the clinical significance of prenatally detected calicectasis, the accuracy of pre-

natal ultrasonography in predicting the level of obstruction, the frequency of associated malformation, and the natural history of the obstructive process during fetal life.

Results

The data base consisted of 97 kidneys from 63 fetuses with suspected congenital hydronephrosis on the basis of gross ultrasonographic appearance. In 56% of cases this was an incidental finding during obstetric ultrasonographic examination for other indications. The remaining 44% of fetuses were referred because of a suspected renal anomaly identified during a prior outside ultrasonographic examination.

Congenital hydronephrosis was confirmed by postnatal evaluation in 45 (71%) of the 63 fetuses. Bilateral lesions were present in 15 (33%) of the 45 infants, for a total of 60 index kidneys. Among unilateral cases the left kidney was more commonly involved (57%). As expected, a strong male predilection was found with a male/female ratio of 4.5:1. A single umbilical arery was present in 3.2% of cases. Major nonrenal malformations were identified in 9.5% of infants with congenital heart disease most commonly observed (Table I).

Ureteropelvic junction obstruction was the most common underlying lesion, accounting for nearly two thirds of all cases (Table II). The ureterovesical junction was the next most common site of obstruction (14%), followed by ureterocele (5%) and a variety of other lesions. The accuracy of fetal ultrasonography in predicting the level of obstruction varied widely by underlying lesion. For example, 97% of ureteropelvic junction obstructions were correctly identified versus only 33% of ureterovesical junction obstructions (Table II).

The natural history of congenital hydronephrosis was established by analyzing data from 39 hydronephrotic kidneys monitored with serial ultrasonographic studies. A graph was established for each kidney; the anteroposterior renal pelvic diameter was plotted against gestational age and compared with a similar nomogram derived from a control population of 137 normal fetuses. Congenital hydronephrosis was considered progressive if the observed slope exceeded that of the reference curve (Fig. 2). With this approach, 14 of 39 obstructive lesions (36%) were considered stable throughout gestation whereas progressive obstruction was noted in 37% (14/39) and some improvement in the remaining 28% (11/39). Amniotic fluid volume was normal in 87% (39/45) of hydronephrotic pregnancies whereas oligohydramnios was noted in four pregnancies (9%) and polyhydramnios in two cases (4%).

Six different ultrasonographic parameters were evaluated to determine the best predictor(s) of postnatally confirmed congenital hydronephrosis and related morbidity.

Anteroposterior renal pelvic diameter. In analyzing the data three different thresholds were examined: ≥4, ≥7, and ≥10 mm (Table III). Before 33 weeks' gestation, a threshold of ≥4 mm was required to achieve a sensitivity of 100%. During the last 7 weeks of pregnancy, a threshold of ≥7 mm could be used while still maintaining a sensitivity of 100%.

Anteroposterior diameter of renal pelvis/kidney ratio. Thresholds of >0.28, >0.30, >0.40, and >0.50 were analyzed (Table IV). An anteroposterior pelvis/kidney ratio of >0.28 was required to achieve a sensitivity of 90% to 100%.

Transverse diameter of renal pelvis/kidney ratio. Thresholds of >0.3, >0.4, and >0.5 were selected for analysis (Table V). The threshold of >0.3 proved most sensitive, identifying 96% to 100% of fetuses with postnatally confirmed congenital hydronephrosis.

Table V. Transverse diameter of pelvis/kidney versus risk of postnatal congenital hydronephrosis

Transverse diameter, pelvis/kidney ratio	*14-23 wk*		*24-32 wk*		*33-42 wk*	
	Sensitivity (%)	*False-positive rate (%)*	*Sensitivity (%)*	*False-positive rate (%)*	*Sensitivity (%)*	*False-positive rate (%)*
>0.30	96	51	100	37	100	26
>0.40	72	51	86	35	88	27
>0.50	52	41	60	31	77	23

Table VI. Kidney circumference/abdominal circumference versus risk of postnatal congenital hydronephrosis

Kidney circumference/abdominal circumference ratio	*14-23 wk*		*24-32 wk*		*33-42 wk*	
	Sensitivity (%)	*False-positive rate (%)*	*Sensitivity (%)*	*False-positive rate (%)*	*Sensitivity (%)*	*False-positive rate (%)*
>0.28	95	49	89	33	59	26
>0.30	90	44	76	32	48	22
>0.32	76	43	58	27	41	0

Kidney/abdominal circumference ratio. Thresholds of >0.28, >0.30, and >0.32 were examined (Table VI). A threshold of >0.28 appeared optimal although sensitivity decreased to only 59% in late pregnancy.

Renal parenchymal thickness. Although ultrasonographically measured parenchymal thickness might potentially reflect cortical atrophy, no threshold that accurately predicted infant outcome could be identified.

Calicectasis. Dilated calyces were noted prenatally in only 47% (28/60) of hydronephrotic kidneys. While not highly sensitive for prenatal diagnosis of postnatally confirmed congenital hydronephrosis, calicectasis did correlate with morbidity. As noted in Table VII, surgery and renal compromise were significantly more common in fetuses with dilated calyces than in fetuses without calicectasis.

Table VII. Impact of calicectasis on postnatal outcome

	Normal calyces	*Dilated calyces*
Kidneys (No.)	32	28
Surgery required (%)	41	79
Renal compromise (%)	28	50
Surgery with or without compromise (%)	56	89

Comment

Ultrasonographic recognition of a prominent fluid collection within the fetal renal pelvis represents a diagnostic dilemma. False-positive diagnosis of fetal hydronephrosis may lead to unwarranted parental anxiety, as well as unnecessary and expensive diagnostic studies after delivery. At the same time failure to recognize and promptly treat clinically significant obstructions may result in impaired renal function. Several ultrasonographic criteria have been proposed for prenatal diagnosis of congenital hydronephrosis; however, this is the first investigation to compare these parameters in the same population and correlate their accuracy in predicting infant outcome.
